In an article by Müller, of Vienna, on a new anomaly of the iris, he described a condition which he calls vitiligo iridis, and which he considers to be an arrest of development belonging to a late period in the development of the organ and confined to a single portion of it. The condition consists of numerous spots scattered all over the iris, corresponding to pits in the stroma. These spots are bluish-gray or grayish-white in color, varying in size from a pin's head upward. The pigment layer is wanting in patches, and here the iris stroma is noticeably thinner. It is a sort of circumscribed achromasia in the pigmentary layer of the iris.

Part X is entirely devoted to a detailed account of the experiments and observations of Deutschmann in regard to the so-called ophthalmia migratoria, and is beautifully illustrated. This article, though long, will amply repay the time spent in its perusal. The experiments have been very carefully made, and the microscopical examinations have been most painstaking.

Another interesting microscopical paper is by Kamocki, upon hyaline degeneration of the conjunctiva, and this is also finely illustrated with colored drawings.

In Part IX embryology is finely illustrated in a paper by Vossius, on congenital anomalies of the eye.

Electricity in Diseases of Women and Obstetrics. By FRANKLIN H. MARTIN, M. D., Professor of Gynecology, Post-graduate Medical School of Chicago, etc. With Illustrations. Chicago: The W. T. Keener Company, 1893. Pp. xiv-278. [Price, \$2.]

THE first four chapters of this work are devoted to a consideration of electricity, including its various forms of magnetism and static and dynamic electricity, as well as the physical properties of the galvanic current. The better-known galvanic cells are then described, and directions are given regarding the selection of currents. Brief chapters are devoted to the galvanic current generated by mechanical energy, to the faradaic current, to the storage battery, to portable and office batteries, to the cautery battery, to the various rheostats employed to control the current that may be taken from an incandescent current used for street lighting, to the galvanometer and milli-ampèremeter, and to poles, cords, and electrodes. It may thus be seen that the author does not assume that his reader is acquainted with the elementary facts of electricity, but presents them in a compact and easily understood manner, these chapters forming the first part of the volume.

The second part first describes electrolysis as a preliminary to the description of Apostoli's method of treating fibroids and the author's modifications thereof. He advocates the necessity of having electrodes of a certain size with certain current-strength, and maintains that by this means he can with a moderate current accomplish accurately and comparatively painlessly the same work at a few sittings that is accomplished at one sitting with a large and painful current. The usual classification of fibroids is given, and attention is called to the different action of electricity on the different forms of these neoplasms. The author gives the histories of a number of patients treated successfully and unsuccessfully by the Apostoli method, and he does not advocate a general employment of this method of treatment.

The treatment of chronic endometritis, chronic endotrachealitis, and uterine hyperplasias by galvanism is carefully described, and the application of this therapeutic procedure is recommended for certain forms of subinvolution and the so-called pelvic cellulitis.

There is a description of the galvanic treatment of uterine, urethral, and rectal strictures and of hæmorrhoids.

A brief chapter is devoted to the treatment of cancer by electricity.

The scope of faradization in gynecology is considered in several chapters.

There are short chapters on the use of the galvano-cautery in gynecology, on the electric bath, and on static electricity.

The author's tone throughout the work is temperate, and the volume will give much valuable and suggestive information to those that have to do gynecological work.

Essentials of Minor Surgery, Bandaging, and Venereal Diseases. Arranged in the Form of Questions and Answers. Prepared especially for Students of Medicine. By EDWARD MARTIN, A. M., M. D., Clinical Professor of Genito-urinary Diseases in the University of Pennsylvania, etc. Second Edition, revised and enlarged. Seventy-eight Illustrations. Philadelphia: W. B. Saunders, 1893. [Price, \$1.] [Saunders's Question Compende, No. 12.]

THE author has taken the opportunity of the appearance of a second edition of this manual to give it such revision as was

requisite to bring it up to the present standard of surgical practice. A number of new illustrations have been added, that have been obtained from the *American Text-book of Surgery*.

Stricture of the Urethra. By G. FRANK LYDSTON, M. D., Professor of the Surgical Diseases of the Genito-urinary Organs in the Chicago College of Physicians and Surgeons, etc. With Seven Full-page Plates and Eighty-five Woodcuts. Chicago: The W. T. Keener Company, 1893. Pp. viii+2 to 334. [Price, \$3.]

THE author states in his modest preface that this volume is essentially a series of class-room lectures upon urethral stricture, unpadded with what he is pleased to denominate the rubbish from the literary dead lumber room.

The lectures, or chapters as they are arranged in this volume, show the author's original method of presenting his facts. In the first chapter, on the anatomy of the urethra, for example, he calls attention to the reason for the disparity in the reported observations on the length of the urethra as being due to the mental condition of the patient and the methods of the observer, summing up his facts in the epigrammatic statement that each urethra is a law unto itself as far as its length is concerned. Or, again, when deprecating what he designates as the "stove-pipe" surgery that assumes that the urethra is a canal through which any instrument ought to go and should be made to go, he urges consultation with a specialist unless the treatment of the case by the general practitioner is likely to prove profitable to the patient as well as to the physician. And the author's statement is not entirely extravagant that "the unfortunates who have been slain or hopelessly crippled by a dirty catheter or sound, in the hands of a dirtier doctor, might, if the truth were known, rival in number those troops of shades with uncured gleet whom Ricord said he met in Purgatory."

The pathology, ætiology, and general treatment of stricture are presented in consonance with our present knowledge, and separate chapters are devoted to dilatation, to division and urethrotomy, to electrolysis, and to the complications and secondary results of stricture.

It is a pleasure to commend the section on urethral fever, that will certainly make the ætiology of this symptom more comprehensible to the student. But we think that the author is too radical when he recommends division or urethrotomy in cases in which urethral fever follows each operation of dilatation. That the urethral fever occurs is sufficient indication of the existence of autogenetic toxæmia, and until the latter is corrected by appropriate general treatment no operative procedure should be instituted. It is the failure to attend to this latter important point that has so often resulted in a fatal issue after urethrotomy or division. The latter operation is described, but the author wisely advises against the employment of what has never been better than an unsurgical procedure, except in a limited class of cases; and we believe in those he is following precedent rather than his better judgment, for external urethrotomy seems to be preferable to division in all forms of stricture of the deep urethra.

The author's presentation of his subject is clear and comprehensive, and the work is necessary to any one desiring the latest information relative to stricture.

The Clinical Use of Prisms and the Decentering of Lenses. By ERNEST E. MADDOX, M. D. Second Edition, revised and enlarged. Bristol: John Wright & Co., 1893.

THE second edition of this little work fully maintains the reputation accorded to the first edition. The first ten chapters con-

tain the purely scientific part of the work, consisting of a statement of the geometrical and optical properties of prisms, the laws of prismetry, prismatic aberration, a description of the various rotating prisms in use, the clinical properties of prisms, and the rules for the decentering of lenses. Chapters XI, XIII, and XIV are especially valuable to the practicing ophthalmologist. Chapter XI, devoted to the study of convergence, is a most admirable presentation of our present knowledge on this subject. Maddox believes that the so-called "muscular asthenopia" of von Graefe is really a central asthenopia in which there is a waste of co-ordinating nervous energy which can be relieved by prisms with their edges out, which lessen the convergence necessary for single vision. He believes it desirable to relieve only a certain portion of the reflex convergence. In every case it is better to study the principles of convergence than to make rules of too arbitrary a nature, for in many cases convex lenses are indicated rather than prisms. The discussion upon "initial convergence," based upon the recognition of a physiological tone in the ocular muscles, is very practical and simple. He believes that divergence, instead of parallelism, is the natural anatomical position of the eyes. The section on accommodative convergence is very simple, and the tests for its examination and recognition are easily made. Maddox's explanation of the benefit derived from the so-called "Dyerizing" plan of treating latent deviations is that it simply trains the efforts of accommodation and convergence to assume broader relations to each other in their work, and in this he is probably correct. His description of the methods employed for deciding the presence or absence of binocular vision is extremely clear and satisfactory, and has the additional advantage of being very brief. The volume is of a convenient size and extremely well printed.

Essentials of Bacteriology: being a Concise and Systematic Introduction to the Study of Micro-organisms for the Use of Students and Practitioners. By M. V. BALL, M. D., Physician to the Eastern State Penitentiary at Philadelphia. Second Edition. With Eighty-one Illustrations, some in Colors, and Five Plates. Philadelphia: W. B. Saunders, 1893. [Price, \$1.] [*Saunders's Question Compende.*]

IN the new edition of this compendium the author has incorporated the discoveries that have been made in bacteriology during the year that elapsed between the appearance of the first and the preparation of the second edition. The author has been very careful in his work, exercising good judgment in the selection of the facts that he has incorporated, and the volume will undoubtedly prove very useful for the purposes for which it is intended.

Minor Surgery and Bandaging, including the Treatment of Fractures and Dislocations, Tracheotomy, Intubation of the Larynx, Ligation of Arteries, and Amputations. By HENRY R. WHARTON, M. D., Demonstrator of Surgery and Lecturer on Surgical Diseases of Children in the University of Pennsylvania, etc. Second Edition, thoroughly revised and enlarged, with Four Hundred and Sixteen Illustrations. Philadelphia: Lea Brothers & Co., 1893. Pp. viii+13 to 529. [Price, \$3.]

THE appearance of a second edition of this work two years after its first publication is an evidence of the professional appreciation of the volume that was predicted in our review of the first edition.

In this edition the author has added sections on the transverse recurrent bandage, on the occipito-frontal bandage, on the arm-and-chest bandage, on the spica bandage of the buttock, on the flannel bandage, on iodol, on bone grafting, on the

use of evaporating lotions in the treatment of fractures, and on Wyeth's method of hip amputation. He has revised the section on the aseptic and antiseptic treatment of wounds, bringing it to the standard of the surgical procedure of to-day.

A number of illustrations have been added, and some new ones have been substituted for those formerly employed.

The volume is complete and in every way worthy of the popularity that has been accorded it.

The Throat and Nose, and their Diseases. With One Hundred and Twenty Illustrations in Color, and Two Hundred and Thirty-five Engravings, designed and executed by the Author, LENNOX BROWNE, F. R. C. S. E., Senior Surgeon to the Central London Throat and Ear Hospital. Fourth Edition. Philadelphia: Lea Brothers & Co., 1893. Pp. xx-734.

The new edition of this standard work, the author states, is necessary because the last edition has been out of print for two years. Profiting by this fact, he has taken the opportunity of revising some details so as to keep the work fully abreast of the recent accessions to laryngological knowledge. The revision is especially noticeable in the section on diseases of the nose, and the author urges that in the condition of the nasal fossa, that constitute the first avenues of the natural breathway, is to be found the key to a right understanding and successful treatment of the majority of faucial, pharyngeal, and laryngeal diseases.

The present edition fully sustains the excellent reputation that this work possesses.

A Practical Treatise on Diseases of the Skin, for the Use of Students and Practitioners. Third Edition, thoroughly revised and enlarged. By JAMES NEVINS HYDE, A. M., M. D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago, etc. Philadelphia: Lea Brothers & Co., 1893. Pp. xix-17 to 802.

It is but ten years since the first edition of this work was published, and yet so thorough has the author's revision been, so numerous are the additions, that the present volume may virtually be considered a new work.

As in the former editions, the author has adhered, in the main, to the classification of skin diseases adopted by the American Dermatological Association.

Among the additions are sections on scarlatiniform erythema, a term designating several different conditions; on dermatitis gangrenosa; on pityriasis rubra pilaris; on epidemic exfoliative dermatitis (Savill's disease); on the parasitic varieties of eczema; on pemphigus vegetans; on keratosis follicularis; on acanthosis nigricans; on angeioneurotic oedema; on acromegaly; on alopecia follicularis; on xanthoma diabeticorum; on leukokeratosis buccalis; and on actinomycosis. The section on tuberculous affections of the skin has been rewritten so as to incorporate the results of the latest investigations on tuberculosis. Thirty-five new diseases are considered in the present edition.

The illustrations have been increased by five plates and twenty-two woodcuts, and they fully sustain the excellent character of the illustrations in the former editions.

The work in its present form can not but continue the reputation it has gained of being one of the foremost of American text-books on dermatology.

A Treatise on the Science and Practice of Midwifery. By W. S. PLAYFAIR, M. D., LL. D., F. R. C. P., Physician-Accoucheur to H. I. and R. H. the Duchess of Edinburgh, etc. Sixth American from the Eighth English Edition. With

Notes and Additions by ROBERT P. HARRIS, A. M., M. D., Honorary Fellow of the American Gynecological Society and of the Philadelphia Obstetrical Society, etc. With Five Plates and Two Hundred and Seventeen Illustrations. Philadelphia: Lea Brothers & Co., 1893. Pp. xx-33 to 697.

THE American editor is well and favorably known as a careful student of this specialty and a patient collector of its statistics. The appearance of this edition, four years after the publication of its predecessor, has enabled Dr. Harris to report the more important advances in those obstetrical methods intended to save the life of the mother and of the child. In this respect the editor and the author are at variance, for the former is an advocate of the conservative surgery attained by Cæsarean section and symphysiotomy rather than the destructive surgery of craniotomy, that is inapplicable to any of a large number of our fellow-countrywomen, because it is forbidden by the Roman Catholic Church.

Dr. Harris's collected statistics of Cæsarean section show that it has saved ninety per cent. of the women, only two out of the last twenty operations in the United States having resulted fatally to the mother. The subperitoneal procedure of the Porro-Cæsarean method showed a mortality of only fourteen per cent. in 1891.

The statistics of symphysiotomy from 1886 to June 1, 1893, show that twenty-five women and thirty-seven children were lost in two hundred and five symphysiotomic deliveries. Dr. Harris does not consider that the danger is from any injury done to the sacro-iliac synchondroses, but rather from the risk of septic poisoning from the wound in the symphysis or from lacerations of the cervix, vagina, or perineum.

The present edition fully sustains the excellent reputation of this standard work.

Anatomy, Descriptive and Surgical. By HENRY GRAY, F. R. S., Fellow of the Royal College of Surgeons, Lecturer on Anatomy at St. George's Hospital Medical School. The Drawings by H. V. CARTER, M. D., late Demonstrator of Anatomy at St. George's Hospital. With Additional Drawings in Later Editions. A New American from the Thirteenth English Edition. Edited by T. PICKERING PICK, Surgeon to and Lecturer on Surgery at St. George's Hospital. Philadelphia: Lea Brothers & Co., 1893. Pp. 24-33 to 1129.

THE thirteenth edition of this well-known work needs no more commendation at our hands than its predecessors have received. Apparently anatomies may come and anatomies may go, but this is perennially a favorite and will go on forever. The only criticism we are tempted to make is that in the section on the spinal cord the surgical anatomy of the different regions is not mentioned. Many of the cuts have been re-engraved, and the volume is an admirable specimen of the engraver's and printer's art.

BOOKS, ETC., RECEIVED.

Supplement to the Reference Handbook of the Medical Sciences. By Various Writers. Illustrated by Chromolithographs and Fine Wood Engravings. Edited by Albert H. Buck, M. D., New York city. Vol. IX. New York: William Wood & Company, 1893. Pp. vii-1076.

A Treatise on the Science and Practice of Midwifery. By W. S. PLAYFAIR, M. D., LL. D., F. R. C. P., Physician-Accoucheur to H. I. and R. H. the Duchess of Edinburgh, etc. Sixth American from the Eighth English Edition. With Notes and Additions by Robert P. Harris, A. M., M. D., Honorary Fellow of the American Gynecological Society and of the Philadel-

phia Obstetrical Society, etc. With Five Plates and Two Hundred and Seventeen Illustrations. Philadelphia: Lea Brothers & Co., 1893. Pp. xx-33 to 697.

New Inventions, etc.

A NEW PORTABLE APPARATUS FOR STERILIZING EYE INSTRUMENTS BY BOILING IN WATER.—AN ALUMINIUM SHIELD FOR PROTECTING THE EYE AFTER CATARACT EXTRACTION.

By JOSEPH A. ANDREWS, M. D.,

OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK.

THE apparatus figured here is intended to serve a useful purpose in sterilizing eye instruments by boiling in water, especially when important operations are done at the homes of patients. The apparatus occupies so little space that it can readily be carried in a small satchel, and is at all times ready for use.

Fig. A represents a ground plan of the entire apparatus. 1 is the outer box for containing the boiler (2) and tray (3), the

FIG. A

FIG. B

FIG. D

FIG. C

FIG. D.—1, Hollow ground stopper drawn out into a tube which terminates in a smooth curved point at 2. The rubber nipple, 3, serves to draw up and inject the fluid contained in the bottle. The ground stopper, 4, closes the hollow stopper, 1, and prevents the fluid in the bottle from becoming contaminated by contact with the rubber nipple, 3, when the bottle is transported. The collar, 5, protects the mouth of the bottle from collections of dust, etc.

latter with a rack and perforated bottom, for receiving the instruments. The boiler (2) has its own cover; it is intended for the instruments only. It is therefore quite distinct from the

other things in the outer case—i. e., lamp, bottles, etc.—the outer case being merely intended to keep everything together.

Fig. B represents the entire apparatus inclosed in its case.

Fig. C shows the tray in the boiler, in place over the lamp, ready for use.

Fig. D shows the bottle used for solutions of cocaine, atropine, and one-per-cent. chloride of sodium. The latter solution is, when boiled, intended for washing out the conjunctival *cul de sac*, thus mechanically cleansing the surface of the mucous membrane.

The solutions are boiled in these bottles; the bottles must, therefore, be blown, not cast in a mold. The bottle is fashioned on a small scale after the one devised by myself for syringing out cortical matter after cataract extraction (see *Transactions of the American Ophthalmological Society*, 1892, p. 455).

Dimensions.—Tray for instruments, five inches wide, six inches long. The rack for the instruments is detachable. The case containing boiler, lamp, etc., is eight inches long, five inches wide, and an inch and five sixteenths deep.

In preparing instruments for an operation, boiling water is poured directly from the kettle into the boiler, and the instruments (except the cataract knife and keratome, which are simply dipped several times in the boiling water and repeatedly firmly wiped with absorbent cotton) are boiled for three minutes. The tray containing the instruments is then lifted out of the water,

the latter at the same time running back into the boiler through the perforated bottom in the tray. The tray, covered, is laid on a clean towel on the table, and in a few seconds the instruments are cool and ready for use.

The shield, represented in Fig. E, is designed to protect the eye against injury after cataract extraction, etc. Being made of thin sheet aluminium, it is very light, and readily bent, if necessary, to adapt it to the shape of the head.

The gauze or flannel bandage having been applied, the shield is held in place

over this by means of a tape which passes through the apertures in its upper part, no sewing being necessary for this purpose.

The apparatus is manufactured by Messrs. Bramhall, Deane, & Co., 264 Water Street, New York, and E. C. Meyrowitz, West Twenty-third Street, who also manufacture the shield.

9 WEST TWENTY-SECOND STREET.

A NEW ETHER INHALER.

By STUYVESANT F. MORRIS, M. D.

So many inhalers for the administration of ether have been presented to the profession that it is with hesitation I offer another. Probably the inhaler most generally used and the best is the Alais. When this latter becomes soiled the bandage has to be changed; the length of time required to do this is a serious objection. The inhaler I present consists of an oblong box five inches and a half long, two inches and a half wide, and three quarters of an inch deep, with perforated covers. Into this are placed a handkerchief or piece of gauze, and a rubber cone five

inches and a half deep, having on the inner side, two inches from the bottom, an elbow of rubber. This is to prevent the box from slipping out of the cone. Etherization with a closed cone, so generally used in our hospitals, is, I think, very objec-

W. F. FORD & CO. N. Y.

tionable, in that asphyxiation is often produced. This one allows a free admixture of air if it is desired. It can be readily cleaned if soiled during an operation by taking out the gauze and washing the box and cone. This can be done in a few seconds. Its size is such that it can be carried in a box or a small satchel. It is so simple in construction that it can not get out of order.

The accompanying cuts show the cone inside out, displaying the rubber elbow. The box, however, is represented without a cover.

16 EAST THIRTIETH STREET.

Miscellany.

The Importance of Early Attention to the Disability caused by Infantile Paralysis.—At a meeting of the New York Academy of Medicine held on November 2d Dr. A. B. Judson read the following paper:

I propose to consider briefly the question whether a certain class of patients should not be committed more entirely and more early than they are to the care of the orthopedic surgeon—a consideration as interesting to the family physician as to the orthopedist, as they meet in a friendly alliance to secure the greatest benefit for their common patient.

I refer to patients disabled by infantile paralysis. The child has passed through the stage of onset. Ergot, electricity, and massage have produced their legitimate effect, and we will say that the eighteen months, which are believed to be the limit of spontaneous recovery from the paralysis, are passed. The friends and the patient, with many grievous misgivings, have become reconciled or at least accustomed to disability and deformity which now seem to change for neither the better nor the worse. What can now be done? The question whether such a patient may not yet receive benefit from the advance of scientific knowledge or from the daily increasing facilities for the application of knowledge will surely spring up in the parental heart.

Now, it is curious to note that the deformity in these cases

is often found, upon analysis, to be a disability more than a deformity. Take a case, for example, in which the knee can not be completely extended. When the patient is sitting there is no deformity, but when he stands the apparent deformity is due to a disability—an inability to extend the knee. How easy it would have been to prevent contraction of the hamstrings by providing for their repeated elongation by complete extension of the knee, easy comparatively for one who has given himself to such details and is habitually mindful of their importance and free from the manifold cares which beset the average practitioner! And it should be borne in mind that cases sometimes occur in which shortening of the tendons begins, in a manner not well understood, at a very early stage, before simple desuetude can be fairly accused of being the author of the mischief. The prevention of muscular and tendinous shortening then should receive attention on the part of the early observer of the case. It is not an obscure and difficult point, but one which has perhaps escaped the consideration to which it is entitled.

To recur to the disabled knee—and this part of the anatomy is used simply as a convenient example to illustrate points in pathology and treatment applicable to all the joints—if the knee is kept extended at those times when walking is attempted, not only are the muscles and tendons kept in normal elongation, but the general welfare of the limb is assured. Neglected patients may be seen in the streets walking laboriously with extension of the knee produced by the hand pressed firmly at every step on the lower part of the thigh when the weight of the body is on that limb. It is doubtful whether this in any case prevents the final resort to a crutch, by the use of which the limb is made to dangle, being carried about as a worse than useless burden, twining limp around the crutch, subject to the painful affections which attack the lower extremities in cold weather in the absence of healthy circulation, and more and more impeding locomotion until, as has happened many times, the adult patient seeks relief and improved locomotor ability in amputation and an artificial limb. If the knee is stiffened mechanically, the pressure of the weight of the body in standing, and the repeated concussion of the limb as the foot strikes the ground in walking and running, will improve the tardy circulation; but beyond this, and better than this, will be the development of unused muscular fibers and special groups of muscles, by whose action important motions will be acquired which would have been impossible if the limb had remained in suspension.

Now, in order to keep the knee firmly extended under the weight of the body in standing and walking, and to give use and development, as far as may be, to the fragmentary muscular system of the limb, apparatus is required; but it will not be obtained without authoritative medical advice and prescription, and, as a rule, the family physician can not be expected to work out the tedious processes incident to treatment of this kind. It falls to the lot of the specialist, who can well bear the inconvenience attending final results which are more or less imperfect, after satisfying himself that he has done all that science permits to be done, and whose daily and hourly mastery of the necessary details has enabled him to reduce perplexing and complicating conditions to familiar routine. Treatment of this kind lies far outside ordinary practice, in which the physician renders such signal service. He makes his diagnosis, advises, prescribes, remains on guard against complications, foresees the crisis and prepares for it, leads the way cheerfully through convalescence; and medical science, so dear to us all, finds but another illustration of its power and beneficence. In one home a wasting fever has been finally resolved and the patient rises in perfect, or even improved, health from a bed where the

grim alternative has been decided in his favor. In another the children have been happily carried through the perils of infection and resume their places at the table. But in the special practice adapted to the cases under consideration there is no fear of a fatal result and no rejoicing, and the object sought is at the best a palliation. But who will say that important service has not been rendered? for it should be remembered that the conservative and plodding practitioner along this line has for an ally one of the most potent influences in Nature in the growth of the body. The popular reliance on this force, expressed in the common question, "Will the child not outgrow the ailment?" whatever it may be, is not always misplaced. Happy the physician who, imparting his confidence to the patient's friends and relying on the exact science of the physician, sees grace and power growing out of deformity and helplessness.

A good general rule in the treatment of deformity in a growing child is to keep the part as near as possible in the desired shape as much of the time, day and night, as is practicable, so that the increment shall be on the right side of the dividing line between the normal and abnormal. The familiar proverb says: "As the twig is bent, the tree's inclined." In the troubles following infantile paralysis the principle should be extended. We should not only persist in keeping the part as near the normal shape as we can, but we should also give as wide play as the crippled condition of the limb will allow to the functions of motion and weight-bearing. From the very earliest attempt to walk, or to make use of the muscles and joints which are imperiled by the cord lesion, extraneous assistance should be afforded. It should not be said offhand that the child is too young. The first and repeated question should be: Is the child not yet old enough, or is he not already giving sufficient evidence of a desire to make use of the questionable muscles and joints to make assistance desirable or necessary?

When efficient treatment is begun it is easily continued. Improved ability is at once appreciated by both parent and child. It is well that such is the fact, for improvement does not stop with infancy or childhood. The process is slow and prosaic, but the benefit can not be overestimated in the opinion of the one who is in the best position to judge of its value. A slight improvement in the gait or an ability to walk a little faster or a little farther without fatigue confers lasting happiness, and the patient and physician are thus encouraged to go on to new achievements until, with one step after another gained, the outcome is an adult well able to follow the ordinary pursuits of life, in place of a being who had looked forward to hopeless dependence.

The Congress of American Physicians and Surgeons.—

A meeting of the executive committee was recently held at the house of the chairman, Dr. Landon Carter Gray, at which there were present Dr. A. L. Loomis, president of the congress; Dr. H. P. Bowditch, representing the Physiological Association; Dr. D. B. St. John Roosa, of the Ophthalmological Association; Dr. Abraham Jacobi, of the Pediatric Association; Dr. P. A. Morrow, of the Dermatological Association; Dr. James B. Walker, of the Climatological Association; Dr. R. W. Taylor, of the Genito-urinary Association; Dr. W. T. Lusk, of the Gynecological Society; Dr. F. J. Shepherd, of the Association of American Anatomists; Dr. L. McLane Tiffany, of the Surgical Association; Dr. W. H. Welch, of the Association of American Physicians; and Dr. Landon Carter Gray, of the Neurological Association.

A local committee of arrangements in Washington was appointed as follows: Dr. S. S. Adams (chairman), represent-

ing the Pediatric Association; Dr. John S. Billings, the Surgical Association; Dr. H. G. Beyer, the Physiological Association; Dr. S. O. Ritchie, the Otological Association; Dr. S. C. Busey, the Gynecological Society; Dr. W. W. Johnson, the Climatological Association; Dr. J. Atkinson, the Dermatological Association; Dr. W. H. Welch, the Association of Physicians; Dr. I. O. Rosse, the Neurological Association; Dr. Samuel Theobald, the Ophthalmological Association; Dr. T. Morris Murray, the Laryngological Association; Dr. D. W. Prentiss, the Genito-urinary Association; and Dr. Frank Baker, the Anatomical Association.

It was arranged that the following subjects should be discussed by the congress at its next meeting in Washington, in the latter part of May, 1894:

The Climatological Association: Sewer Gas. The Genito-urinary Association: The Surgical Kidney in its Clinical Aspects. The Dermatological Association: Leprosy in the United States. The Laryngological Association: Intranasal Surgery. The Gynecological Society: The Conservative Treatment of the Female Pelvic Organs. The Neurological Association: The Effects of Infectious Processes on the Nervous System. One association is yet to select a subject for discussion.

Dr. W. H. Carmalt, of New Haven, resigned from the subcommittee deputed to take charge of the organization of the congress, and Dr. W. H. Welch, of Baltimore, was appointed in his place, so that the committee now consists of Dr. A. L. Loomis, president of the congress; Dr. Landon Carter Gray, chairman of the executive committee; Dr. Newton M. Shaffer, secretary of the executive committee, and Dr. W. H. Welch.

The Southern Surgical and Gynecological Association.

—The sixth annual meeting will be held in New Orleans on Tuesday, Wednesday, and Thursday, November 14th, 15th, and 16th, under the presidency of Dr. Bedford Brown, of Alexandria, Va. The programme includes the following:

A memorial address on Dr. Ephraim McDowell, by Dr. McMurry, of Louisville; The Diagnosis of Pelvic Inflammatory Diseases, by Dr. Howard A. Kelly, of Baltimore; The Treatment of Pyosalpinx, by Dr. Cornelius Kollock, of Cheraw, S. C.; The Incision in Abdominal Section—How to Close it—Post-operative Complications about it, by Dr. Joseph Price, of Philadelphia; The Etiology and Treatment of Post-operative Ventral Hernia, by Dr. Charles A. L. Reed, of Cincinnati; The Vaginal Method as compared with the Abdominal in Operations on the Uterus and its Appendages, by Dr. George J. Engelmann, of St. Louis; The Best Time to Operate in Appendicitis, by Dr. A. M. Cartledge, of Louisville; An Extraperitoneal Method of Operating in certain Cases of Appendicitis, by Dr. Bacon Saunders, of Fort Worth, Texas; Intracranial Neurectomy and Removal of the Gasserian Ganglion, with Report of Cases, by Dr. Louis McLane Tiffany, of Baltimore; Contusion of the Brain, by Dr. J. B. Murfree, of Murfreesboro, Tenn.; Trephining as a Cure for Traumatic Epilepsy, by Dr. John T. Chapman, of Bessemer, Ala.; Some Remarks on the Treatment of Epilepsy, by Dr. B. E. Hadra, of Galveston; A Contribution to the Study of the Prostate, by Dr. G. Frank Lydston, of Chicago; The Management of the Episcytic Fistula in Cases of Enlarged Prostate, by Dr. J. D. S. Davis, of Birmingham, Ala.; The Choice of Operations for Stone in the Urinary Bladder, by Dr. W. T. Briggs, of Nashville; Suprapubic Cystotomy, by Dr. B. W. Taylor, of Columbia, S. C.; Conditions Modifying the Prognosis in Gunshot Wounds of the Abdomen, by Dr. A. B. Miles, of New Orleans; The Treatment of Gunshot Wounds, with Report of Cases, by Dr. W. F. Westmoreland, of Atlanta, Ga.; How to deal with Gunshot Wounds safely without Delay, by Dr. W. L. Robinson, of Danville, Va.; Laparotomy in Gen-

eral Surgery—Report of Twenty-two Cases, by Dr. W. B. Rogers, of Memphis, Tenn.; Celiotomy, with Report of Cases, by Dr. W. H. Watben, of Louisville; Hypertrophy of the Omentum in Hernia, with Specimen, by Dr. G. A. Baxter, of Chattanooga; Wyeth's Bloodless Method in Amputation at the Hip, by Dr. F. W. Parham, of New Orleans; The President's Annual Address (The Southern Surgical and Gynecological Association, its Origin, Objects, and Aims); Cancer: its Etiology and Treatment, by Dr. W. L. Rodman, of Louisville; Operative Procedures for Carcinomatous Tumors of the Breast, by Dr. J. McFadden Gaston, of Atlanta; Wounds of the Bladder, their Recognition and Management, by Dr. Richard Douglas, of Nashville; Fibroid Tumors complicated with Pregnancy, by Dr. W. D. Haggard, of Nashville; The Diagnosis of some Abdominal Tumors supposed to be Ovarian, by Dr. James Goggans of Alexander City, Ala.; Rhinoplastic Operations, by Dr. W. S. Elkin, of Atlanta; Sarcomata of the Peripheral Nerves, with Report of a Case, by Dr. W. O. Roberts, of Louisville; Division of the Cervix Uteri, by Dr. H. P. C. Wilson, of Baltimore; Some Experiments with the Galvanic Current on the Endometrium, by Dr. H. Berlin, of Chattanooga; A Combination of Carbolic Acid and Camphor as an Antiseptic, by Dr. W. Perrin Nicolson, of Atlanta; A Case of Popliteal Aneurysm, by Dr. R. M. Cunningham, of Pratt City, Ala.; The Present Status of Ureteral Surgery, by Dr. A. Dixon, of Henderson, Ky.; Operative Procedures for Calculi in the Pelvis of the Kidney, by Dr. W. E. B. Davis, of Birmingham, Ala.; Two Unique Cases in Abdominal Surgery and Obstetrics, by Dr. B. P. Moore, of Macon, Ga.; Four Cases of Hysterectomy by Baer's Method, by Dr. J. Taber Johnson, of Washington, D. C.; Placenta Prævia, by Dr. George Ross, of Richmond; Some Interesting Cases from Surgical Practice, by Dr. F. W. Parham, of New Orleans; Report of Surgical Cases, by Dr. W. H. H. Cobb, of Goldsboro, N. C.; The Treatment of Stone in the Ductus Communis Choledochus, by Dr. W. E. B. Davis, of Birmingham, Ala.

Poisoning by a Belladonna Plaster.—In the November number of the *American Journal of the Medical Sciences* Dr. Ernest E. Maddox, of Edinburgh, relates the case of Miss P., aged about thirty years, a music teacher, who had been sent to him by her physician on account of obscure eye symptoms.

Her complaint was that on rising one morning she found a mist over her vision, and found that she could not read unless she held the book at a good distance. This was on a Monday, but during the week the symptoms were ameliorated by taking a dose of Gregory's mixture. On Sunday, however, they began to return, and by Monday were as bad as ever. On Tuesday she came to consult him. She looked flushed, and her eyes had an unnatural brightness; the pupils were not larger than they often are in those who, like herself, have slight myopia.

What aroused Dr. Maddox's suspicion was that she was always moving her mouth about in want of saliva, and on inquiry she said that her mouth and throat were painfully dry. Her near point of vision was found to be not nearer than a half-metre, so that, as she had 0.75 D. of myopia, her range of accommodation was only 1.25 D., instead of being, as it should be at her age, 7 D.

As the author felt sure that belladonna must be accountable for the symptoms, a searching inquiry was made as to the possibility of her having had it in some prescription or liniment, but all such possibility was denied.

At last she volunteered the confession that she wore a plaster over the lower part of the back, unknown to her physician, and that it was possible this might contain belladonna. Inquiry into her other bodily symptoms placed it so beyond doubt

that the suspicion would prove correct that she was simply ordered to remove the plaster and take a purge. This she did, with the result that the symptoms rapidly disappeared, though, even eighteen days afterward when she called again, the near point had not been quite recovered, and some of the nervous symptoms had not completely disappeared.

The symptoms which Dr. Maddox had carefully noted when she first came were so well marked, and many of them so characteristic, that he thought them worth recording as a study of the physiological action of belladonna. Besides dryness of the mouth and throat, her eyes felt dry and her skin also. Her pulse was 106, and the apex beat of the heart very strong and diffused. This, the author remarks, is well known to be due to paralysis of the cardio-inhibitory terminations of the vagus. On inquiring about her flushed face, she said she was naturally rather pale, adding, "I never have such a color as I have just now?" Her face felt hot. The eyes appeared smaller, and had a piercing look; to relieve their unpleasant dryness she had been obliged to bathe them with milk and water. She said her eyes seemed to have retreated more into their sockets; this Dr. Maddox thought quite possible, reflecting that belladonna often relieved exophthalmic goitre, and might do so by paralyzing the unstriated muscle behind the globe. He did not think it well, however, to attach too much importance to the observation of a patient on this point, for the mere dilatation of the pupil might deceive one, and make him think the eye looked smaller or more deeply sunk. The patient had well-marked accommodative micropsia, and complained spontaneously of it, saying, "A sixpence looks like a threepenny piece." Her color sensations had an abnormal permanency, so that if she looked at anything red or blue the next object she looked at appeared to be of the same color. This, says Dr. Maddox, is an interesting phenomenon because it is sometimes met with in individuals otherwise normal. He has met with one very well-marked case of such abnormal persistency of color sensation. It appears to be one form of hyperæsthesia of the retina, unless, indeed, its seat is in the nervous centers. Closely allied to this are the mental hallucinations so characteristic of belladonna. One night the patient called her sister's attention to a light shining in at the window, but her sister could see nothing. At other times she thought she saw dark objects. There was hyperæsthesia also of the other senses, so that any disagreeable odor appeared far worse than usual, and noises were unbearable. This keenness of sensation perhaps accounted for the fact that she could not sleep well, but kept waking up every hour. Her natural "nervousness" had been greatly increased by the belladonna; she had become "dull and desponding," life seeming miserable to her during the night; there was also loss of self-confidence, and a feeling as if it were not safe to venture out into the streets alone; she became taciturn, and yet irritable with her pupils; could not remember the day of the week, thinking, for instance, on Wednesday that the day before was Sunday. She would cross the street rather than meet with her friends, from a sense of timidity. Her locomotor equilibration seemed affected, for on rising in the morning she felt giddy and disconcerted on putting her feet on the floor—feet and limbs not seeming to move as they used to; "less agility in movement," and, on walking, felt as if her foot needed putting down a second time. These symptoms, says Dr. Maddox, are interesting as being distantly related to some of those in locomotor ataxia, being, however, functional instead of organic.

The bladder symptoms were almost pathognomonic of belladonna poisoning, and are of interest in connection with the undoubted service of this drug in the enuresis of children. She had frequent desire for micturition, having to rise three or four times at night, and passing much more than usual, very pale, and occupying a long time in its evacuation by a thin stream,

with complete intermissions as though micturition were over, then beginning again. This, the author thinks, probably points to the muscular fiber of the "detrusor urinae" being semi-paralyzed. The copious flow of pale urine, he adds, reminding one of hysteria and of those nervous headaches associated with the same hyperæsthesia of the senses, was no doubt nervous in its origin, unless, indeed, it was, as Dr. Haig would have us suppose, a question of the action of belladonna on the vital chemistry of uric acid.

The plaster was found to be made by one of those firms who pride themselves on the excellency of their belladonna plasters, and who exhibit the results of tests to show how much more belladonna they contain than the official plasters. The case recorded shows there is a limit to excellency of this kind, and that there is need for caution not to carry it too far.

A Surgeon's Nerve.—The following is from a recent article in *Longmans' Magazine*: "It is the common belief that a surgeon must possess what is spoken of as an extraordinary good nerve, and you may perhaps doubt if you possess this. At the same time you must bear in mind that in the case of a surgeon the coolness or calmness which is so admirable and necessary in an operation does not imply the possession of any remarkable personal quality, but it is the simplest result of a complete knowledge of what he is doing. It is rather the natural outcome of his accurate familiarity of anatomy, and his daily habit. A trooper would require a very fine nerve to go to a masthead, or a sailor to ride an unmanageable horse across a country, but a sailor's confidence aloft is due more to a matter of habit than to any particular amount of courage. In saying this, I do not wish to depreciate the calmness of the surgeon in the face of difficulties, but I may tell you quite plainly that if you haven't enough courage to be a surgeon I should be very much ashamed of you, and you would turn out to be a very poor creature, whatever occupation you might follow. Still this fact remains, and you may perhaps be interested to hear that I, who have known many good surgeons, have never seen one who has not possessed a very fine courage. In short, a very good surgeon is, in my humble opinion, a very fine fellow, and when I see (as I do see) the extraordinary achievements of modern surgery, I am very proud of belonging to a profession which has made life so much more endurable and prolonged to the human race. So, possibly, the great fascination which surgery no doubt possesses to many, appeals more strongly to men of courage and determination than to those persons of more weakly constituted minds, or to those who are less vertebrate altogether."

The late Dr. Charles Slover Allen.—The Society of the Alumni of Charity Hospital, at the last stated meeting, adopted the following preamble and resolutions:

Whereas, In the death of Dr. Allen we lose a valued and esteemed associate and friend, a faithful student and accomplished member of our profession; and

Whereas, We acknowledge his friendly interest and the stimulus of his high ideals in our profession and as a gentleman. It is therefore,

Resolved, That we express our sincere and heartfelt sorrow at his death. And further it is

Resolved, That we tender to his bereaved family our profound sympathy. And further it is

Resolved, That a copy of these resolutions be sent to the bereaved family and to the medical journals and spread upon the minutes of the society.

AFFECTIONS OF
THE TESTICLES AND THEIR APPENDAGES
IN HEREDITARY SYPHILIS.*

By R. W. TAYLOR, M. D.,

CLINICAL PROFESSOR OF VENEREAL DISEASES
AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THOUGH it was formerly stated by Zeissl, Hill, and others that the testicles are not affected in hereditary syphilis, there is to-day so much evidence from many careful observers that syphilis does attack these organs in hereditarily infected children that it is almost unnecessary to mention this old-time contention. My own experience is sufficient to warrant me in offering a succinct account of these affections, but I have availed myself of a rich literature in order to more thoroughly elaborate this subject.

The following selected personal cases are worthy of study:

CASE I.—Child, aged three months, fairly well nourished; father syphilitic eighteen months, mother seemingly in perfect health. Shortly after birth snuffles and a papular eruption on the buttocks, legs, and forearms were observed, as well as condylomata about the anus. The child received little if any specific treatment. When ten weeks old the mother noticed that the left testicle was swollen. On examination, the scrotum was red and somewhat indamed. The testis was as large as a nutmeg, hard, firm, perfectly smooth, and painless on moderate pressure. There was slight hydrocele recognizable by palpation, but not by the light test. No involvement of the epididymis or cord. Under the influence of mixed treatment in goodly doses, aided by local daily frictions of white precipitate ointment, the testicle subsided to its normal size in two months.

CASE II.—Child, aged ten months, thin and cachectic, born of parents the victims of recent and irregularly treated syphilis (infection dated about eighteen months before the child's birth), presented swellings at the diaphyso-epiphyseal junctions of the radius and ulna of both arms and of the testes. The right testis was as large as an olive and the left was fully as large as an unbroken filbert. These organs were hard, firm, perfectly smooth, and could be freely handled without discomfort to the child. The bone lesions were tender and painful. There was distinct enlargement of the globus major of the right testicle and a diffuse enlargement of the whole epididymis of the left side. The vas and cord were seemingly normal. There was some hyperæmia of the scrotum, but it was neither inflamed nor painful. Though carefully treated and well nourished, the child improved very slowly under general and local treatment, as in Case I. At the end of nine months the right testicle was seemingly of normal size and healthy in structure. The left testicle from time to time swelled, seeming to resist the influence of the treatment. The affection pursued this course for fully six months; then resolution began which resulted in complete atrophy of the organ. It then felt like a little mass of fat at the end of the vas.

CASE III was that of a child aged thirteen months, thin and wan-looking, like a little old man, born of a mother having a

distinct history of syphilis and of two previous early miscarriages. This child had been treated after birth for fully four months with small doses of gray powder with the effect of dissipating its cutaneous and mucous lesions. When ten months old its mother noticed that the left testis was swollen to the size of a plum. The gray powder was then resumed without benefit. The swelling continued to increase and attained the size of a large walnut. Examination showed that the organ was hard and firm and that its surface was studded with a large number of small nodules with several larger ones of the size of a split pea. A decided enlargement of the whole epididymis and of about half an inch of the vas deferens was felt. Frictions of mild mercurial ointment were used and the mixed treatment was given internally in full doses. The resolution of the morbid process was very slow. Little diminution in the size of the swelling was observed for three months; then the organ gradually grew smaller, yet fully a year elapsed before, upon careful examination and comparison with its fellow, it could be pronounced normal. During this time slight recurrences were noted. Four years afterward, the child was found to be healthy, and no abnormality could be detected in the previously affected testis.

CASE IV.—A child aged two years and a half, the off-spring of parents syphilitic fully two years before its birth. This child had many and varied lesions of the skin, mucous membranes, bones, and joints. It was energetically treated for about eight months and after that mercurials were given irregularly. When two years old the right testis was found to be as large as a walnut. It caused the child no suffering and the organ could be handled without any flinching. When two months old the swelling became larger and adherent to the scrotum. Within a month an abscess formed and from a circular hole in the scrotum half an inch in diameter a grayish red, fungating mass protruded fully half an inch. At this time the child seemed to suffer very little and only winced slightly when the organ was carefully explored. Active internal medication was administered, and the fungating mass was cauterized and dressed with mercurial ointment. In about four months a cure was effected. The testis was then about the size of a pea, but adherent to the scrotal wall. In this case the left testis seemed slightly swollen and affected with hydrocele, both of which conditions subsided under the influence of the treatment. In neither testis was the epididymis involved.

CASE V.—A child, sixteen months old, fairly well nourished and developed, the offspring of a syphilitic father (infection two years old) and a seemingly healthy mother, had in its early months roseola in plaques about the buttocks, a large generalized papular syphilide, and buccal mucous patches. It was treated with inunctions and gray powder for six months. When about a year old its mother noticed that its left testis was enlarged, but, as it caused no pain or uneasiness, she paid no attention to it. Four months later (the sixteenth month of life) the child began to suffer at night and it was found that its left humerus just at and above the elbow joint and the right tibia and fibula above the ankle joint were swollen and painful. At this time examination showed that the left testis was indolently swollen to the size of a Lima bean and that the epididymis was enlarged in a crescent form to the size of a clay-pipe stem, and that the swelling extended for half an inch up the vas deferens. Active general and local mercurial treatment caused a resolution of these lesions in three months. The swelling in the testis was the first to disappear, while that of the epididymis and vas subsided slowly. When the child was two years old no appreciable change could be noted in the testis and epididymis.

* Read before the American Association of Genito-urinary Surgeons at its seventh annual meeting.

CASE VI.—A boy, fifteen years old, had a smooth, hard, painless swelling of both testes which had begun six months previous. They were of the size of a walnut. The epididymes could not be made out by examination, for they seemed to be spread out over the testes as mace is placed in relation to the nutmeg. The vasa deferentia were normal. A treatment occupying fully six months with iodide of potassium internally and mercurial ointment externally was required to produce resolution in these swellings.

The boy was small for his age, but well developed. His parents were in the active stage of syphilis at the date of his birth. He had when an infant keratitis of the right eye, which left a small patch of opacity of the cornea, a middle-ear disease, which caused total deafness, and later on developed typical notched teeth.

These cases present all the salient features and most of the minor and accessory ones of these affections, and are, I think, a satisfactory basis for deduction.

The most common affection is orchitis, and while inflammation of the epididymis is sometimes observed, it is almost always as a complication of orchitis. Involvement of the vas deferens is quite uncommon, but occurs as a complication of the orchitis epididymitis. Neither of these affections is really of frequent occurrence, as shown by the fact that in literature something like fifty cases are more or less fully described or alluded to. Testicular affections are among the rarer manifestations of hereditary syphilis. Pathologically, the testicular lesion has been recognized by Hutinel* as early as the ninth and twenty-third days of birth. Clinically, however, it is seen generally in children from three to six and twelve months old, and in diminishing frequency in the second or third years. Somewhat exceptionally it is seen in later years, as in my sixth case at fifteen, and in a case mentioned by Fournier† at twenty-four. My own experience goes to show that these lesions occur in children the offspring of one or both parents in a tolerably active condition of syphilis, and in many of the reported cases the conditions were similar.

Clinical History.—The orchitis begins slowly and insidiously. No pain is felt by the child, and attention is not called to the diseased organ until its dimensions have become so marked as to attract the notice of the mother or nurse. As usually seen in practice, the testis is of the size of a pigeon's egg, of a small marble, of a shelled filbert, of an olive, or even of a walnut, but it is usually of an ovoid shape. As a rule, the organ is not large, and in the majority of cases reported it was of the size of a shelled or of an unbroken filbert. In other words, there is not a tendency to the development of conspicuously large tumors. To the touch the swelled testis is hard and firm (less hard and ligneous than in the adult), indolent, painless, and decidedly heavy. It can usually be handled with impunity. In some cases there is concomitant hyperæmia of the scrotum. In rather rare instances the surface of the tunica albuginea is uneven and irregular and gives the sensation as if small shot or split peas were seated in its superficies.

The epididymis may be slightly or considerably enlarged, in part or in whole. The swelling is smooth and firm and pressure upon it sometimes causes pain. The enlargement of the vas is similar in all respects to that of the epididymis. The fact of the coincident involvement of the epididymis has been clearly brought out microscopically and clinically in an admirable paper by George Carpenter.*

As a general rule, the enlargement of the epididymis or vas is an accompaniment of a testicular lesion. Comby,† however, reports the case of a child the subject of hereditary syphilis, six weeks old, in whom the epididymis was especially involved. This would seem to show that the epididymis alone may be attacked.

These affections, uninfluenced by treatment, usually run an uneventful course and may end in resolution or in atrophy, particularly of the gland substance. This was well shown in my second case, in which the testis was reduced to a small mass of fibrous tissue. Lewin‡ reports, as an instance of atrophy of the testes from hereditary syphilis, the case of a man, eighteen years old, whose testicles were the size of a child's, who was puerile in demeanor and looked like a boy of fourteen. Réclus* speaks of a case of a patient (age not stated) considered by Parrot and Fournier to be the victim of hereditary syphilis, in whom a gland of the size of a small nut and of great firmness was present. Facts therefore warrant the statement that hereditary syphilis, like traumatism, mumps, and varicocele, may lead to atrophy of the testes. As a general rule, it may be stated that atrophy is the chief form of degeneration in this form of orchitis. In somewhat rare instances fungus of the testes is observed, and it follows the same chronic, rebellious course that it does in the adult. Abscess and necrosis of the testes also occur, in which case we observe a sinus in the scrotum (which may be much inflamed) which leads down to a pus cavity of varying size in the gland itself. I once saw a case of this kind in consultation which was cured by careful treatment. If treated early and vigorously, resolution may be brought about and a testis, more or less damaged, may be left. It is always well to try energetic local and general treatment before thinking of ablation.

Hydrocele is a more frequent complication than has heretofore been conceded. It may be slight or well marked. Its existence in the infant should always excite interest and its origin in syphilis or tuberculosis should be established.

Carpenter reports three cases of hereditary syphilis in which there was hydrocele of the cord, but no appreciable testicular lesion. This affection of the cord might be a coincidence, but Carpenter says "there is just a probability that hydrocele of the cord may in some instances owe its origin to congenital syphilis."

The concomitants of these testicular affections vary according to the age of the child and the intensity of the in-

* *De la syphilis du testicule*, Paris, 1882, p. 149 et seq.

fection. In very early months roseola, papular syphilides, mucous patches, eye, ear, and bone lesions may be also present. In later months there will be fewer and perhaps no concomitants. But there may be bone or joint lesions, and perhaps cutaneous or mucous lesions in sparse and limited development.

Diagnosis.—As a rule, an intelligent study of a case of testicular lesion in a young child will lead to a correct diagnosis. It is necessary to obtain the history of both father and mother, if possible, and then that of the child. In the early months of hereditary syphilis it may quite generally be possible to gain a knowledge or observe a vestige or sequela of some characteristic lesion, or to see some lesion itself. In this event the diagnosis will be easy. When, however, for any cause, we can obtain no information concerning the father or mother, and the child is free from all syphilitic lesions or their traces, difficulty is experienced. Then we must consider the character of the tumor and see whether it conforms to the description already given. Deschamps,* as well as Hutinel, lays stress on the fact that in syphilis the testes are usually both involved, while in tuberculosis commonly but one is affected. This, however, can not be accepted as a general rule, since we not uncommonly find that the syphilitic affection is unilateral. Then, again, too much stress can not be laid upon the condition of the epididymis and vas. In syphilis these appendages may be moderately involved in whole or in part; in tuberculosis it is common to find them much enlarged and sometimes nodulated. When, therefore, we see a case in which there is a unilateral swelling, very marked enlargement of the epididymis, and perhaps of the vas, particularly if the enlargement is rugose or nodulated, and when the testicular lesion is less developed, we may suspect syphilis. In all such cases it is absolutely necessary to examine the prostate and seminal vesicles by rectal touch, and if they also are found to be swollen, the presumption will be warranted that the case is one of tuberculosis. On the other hand, freedom of these structures from disease points in a measure to the existence of syphilis.

No absolute criterion can be drawn from the conditions attending the invasion of the disease. In syphilis the enlargement, as a rule, takes place slowly, but sometimes rather rapidly. In tuberculosis the invasion may be slow and insidious also. But it is well to remember, as Jullien† has shown in his admirable article, that the most

common mode of invasion is the brusque and rapid, attended with marked inflammatory symptoms. This is rarely, if ever, seen in syphilis.

While, therefore, in most cases a clear diagnosis may be made, instances will occur in which it is impossible to say whether the lesion is syphilitic or tuberculous. This point has been prominently brought out by Hutinel and Deschamps, and also by Carpenter and Colecott Fox. These observers report cases in which the syphilitic history is clear and the testicular symptoms point to that origin, yet intelligent and active antisymphilitic treatment fails to produce resolution. In these cases we observe what is so frequently seen in adults—namely, a tubercular infection in a syphilitic subject. This is common in many organs and tissues, notably the lungs, bones, joints, meninges, and testes. It is always well, therefore, to remember this frequently occurring mixed infection. Carpenter very properly states that a thickened, indurated, and enlarged vas is strongly indicative of tuberculosis. The same may be said of cases in which there are multiple ulcerations and adhesions of the scrotum to the testicles.

It is well to remember that the testes of young children are sometimes the seat of carcinoma, encephaloid cancer, and sarcoma. These malignant growths are usually seen toward the end of the first year of life and later. They are, as a rule, of rapid development, of large size (that of a hen's egg, a mandarin, and larger), may be accompanied by inguinal adenopathy and usually more or less pain, and always lead to death sooner or later.

Pathological Anatomy.—The histology of the diseased testicle in hereditary syphilis has been studied by Parrot, Hutinel, Réclus, and Carpenter. The lesion is an interstitial and diffuse collection of round embryonic cells resembling white blood-cells. In the interstitial form, in which the gland may not be perceptibly enlarged, the cell growth results in small tumors of various sizes, irregularly placed around the arterioles which traverse the trabeculae. In other words, it is the same coat-sleeve infiltration which we see in the adult. In the diffuse form, in which the organ is much enlarged, a smaller cell growth is found permeating the meshes of its connective tissue generally. The process begins at the mediastinum testis, follows the vessels of the trabeculae between the seminiferous tubules, and finally results in hypertrophy and sclerosis of the organ, with partial or entire obliteration of the tubules, whose lining epithelium undergoes granulo-fatty degeneration. Fatty degeneration and final absorption of the new growth take place, resulting in atrophy and, in rare cases, in complete destruction of the organ. Probably the cases which are attributed to arrest of development, in which the testis is small or entirely absent, are those in which the organ has been attacked in early life by hereditary syphilis. It is probable that the ovaries may be attacked in a similar manner to the testicles.

Gummata of the testicle in the hereditarily syphilitic infant are very rare. Hutchinson* showed at the meeting of the London Pathological Society a specimen of gumma

* Tuberculose du testicule chez les enfants. *Arch. gén. de méd.*, vol. i, 1891, p. 257 et seq.

† De la tuberculose testiculaire chez les enfants. *Arch. gén. de méd.*, April, 1890. It may be interesting to note that in twenty of Jullien's cases "sixteen occurred in children of less than five years of age, six of them were less than one year old, and six ranged from one to two years. Of the former, one was one month old and two were two months old when the disease was detected. Giraldès (*Leçons cliniques sur les maladies chirurgicales des enfants*, 1869, p. 524) has recorded the cases of infants of a few days only, and Dreshfield (*British Medical Journal*, 1884, p. 860) has observed a case of congenital tuberculosis of the testicle. In four observations by M. Lannois (*Revue mensuelle des maladies de l'enfance*, 1883, p. 528) the testicular tuberculosis appeared at five months, six months, seven months, and thirteen months of age." (Quoted from Carpenter, *op. cit.*).

* *Transactions*, London, vol. xxi, p. 192.

of the testis from a boy the subject of hereditary syphilis. The testis was much enlarged and thoroughly infiltrated with a growth of opaque yellow color. I have failed to find mention of other similar cases.

Henoch* examined, after death, the testes of an hereditarily syphilitic boy, and found extensive connective-tissue hypertrophy of the corpus Highmori. Carpenter also found interstitial new growth in the epididymis.

Treatment.—My experience in fifteen cases convinced me that the mixed treatment in goodly and increasing doses was most efficient in these testicular lesions, as it is in the bone and joint lesions of hereditary syphilis. I was often much surprised at the large doses which infants could take with impunity and marked benefit. This treatment, with intermissions, should be kept up at least two or three years. I am not in accord with Carpenter and other English authors who pin their faith on gray powder. This drug may be useful in the exanthematous stage or state of hereditary syphilis, but it has in my hands proved very feeble and often inert in the lesions of the fibrous tissues and bones.

Locally, much good can be derived from mercurial frictions to the scrotum, using, with great care as to the avoidance of dermatitis, white precipitate, or blue ointment. When the organ is much affected with degenerative processes ablation may be necessary.

40 WEST TWENTY-FIRST STREET.

"THE SPHYGMOGRAPH AS AN INSTRUMENT OF PRECISION."

(WITH APOLOGIES TO DR. LEONHARDT.)

By WILLIAM A. HAMMOND, M. D.,
SURGEON GENERAL, U. S. ARMY (RETIRED LIST).

If Dr. Leonhardt will kindly pardon my appropriation of the title of his contribution to the *New York Medical Journal*, August 26, 1893, I will promise never again to offend in this direction. I do not think I have ever before availed myself of his syntactical acumen, and I would not do so now except for the fact that the title of his paper, after having served his purpose in one direction, is equally appropriate to express my views in another directly opposite direction. It is one of those beautiful examples, in which the English language abounds, of the use of the same words to denote diametrically contrary ideas.

But, on reading Dr. Leonhardt's article, I was impressed with the conviction that the title he employed had very little to do with the object he had in view, which was not so much to descant on the certainty or uncertainty of the results obtained by the sphygmograph as to show that I had in my communication to the *New York Medical Journal*, July 1, 1893, entitled *A Further Contribution to the Subject of Animal Extracts*, committed errors which to a great

extent lessened the value of the results obtained. Before proceeding to discuss the question of the value of the sphygmograph, it will be proper for me to clear myself from these aspersions on my accuracy of statement so far as may be in my power.

I said that I had used Marey's sphygmograph for over thirty years. Absolute exactness would have required me to say about "twenty-eight years." I bought one in Paris in the latter part of the autumn of 1865, and brought it with me to this country in the spring of 1866.

I said that I had used Pond's sphygmograph for more than twenty years. I have two of Pond's instruments, one being among the first he ever made, the other, with improvements, purchased a year or two afterward. I was under the impression, and still am (notwithstanding Dr. Leonhardt says I am three or four years out of the way), that I have owned the first named sphygmograph for over twenty years. Perhaps I am mistaken; I am open to conviction on this point, if Dr. Leonhardt or any one else thinks it worth while to discuss the question further. But what does it matter whether I have owned Marey's instrument for twenty-eight years instead of thirty, or Pond's for seventeen years instead of twenty. Dr. Leonhardt quibbles; he should bear in mind that such points are non-essentials, and that there is a legal maxim applicable to him in this connection which I commend to his serious consideration should he get into another controversy: *De minimis non curat lex*.

But he himself, like most people who set out to correct others, is not guiltless of the very fault he attributes to me. He says: While I do not profess to know all that is to be known on the subject of sphygmography, I am in possession of a few facts that every schoolboy ought to know." This, taken seriously, would be a very ridiculous expression, for, of course, no schoolboy ought to or does know anything about the sphygmograph, unless it may be some phenomenal youth who is so fortunate as to have such a devotee of the instrument as Dr. Leonhardt for his teacher.

In the next place, Dr. Leonhardt finds fault with my statement that "a less vertical upstroke shows increased force." This is true of Marey's instrument, with which the tracings he criticises were made. It probably is not true of Dudgeon's sphygmograph, to which apparatus Dr. Leonhardt pins his faith, but with which, as I have said in my pre-

vious paper, I have no acquaintance. Now, without bringing my own tracings into the question, I submit the above, which I take from Brondel, whose authority Dr. Leonhardt will probably not dispute. The upper one is a tracing made before the administration of pilocarpine. The other

* Ueber Syphilis der Hoden bei kleineren Kindern. *Deutsch. Zeitsch. f. pract. Med.*, 1877, No. 2.

represents a tracing made after 0.02 grm. of the drug had been given hypodermically.

Dr. Leonhardt will not, I think, contend that pilocarpine strengthens the heart, yet we see that the upstroke of the tracing taken after that medicine had been injected is so excessively vertical, if I may use the expression, that it is something in this respect like the attitude of a pompous man in his rigidly erect position. As the inventor of a new cannon said when asked about the recoil: "Gentlemen, there is no recoil backward to this gun; if anything, it recoils a little forward."

In my statement that "the distance between any two upstrokes is shorter when the recording surface moves rapidly, and longer when it moves slowly," I was the victim of heterophemy, as doubtless Dr. Leonhardt himself is at times. A cursory examination of the tracings which I gave as illustrative of the action of cardine would have shown him that I meant the very reverse of what I said. But it is in just such matters as this that he is at his best, and he is entirely welcome to all the glory to be derived from such a style of criticism.

Now, in regard to the value of the sphygmograph, I have never put much confidence in it. The conditions of its employment are so variable that it is difficult, except in very pronounced cases of disease or functional derangement, to get indications approaching accuracy and that do not vary with each application of the instrument. As to comparing the results obtained by one kind of sphygmograph with those obtained by another, nothing is more absurd. Dudgeon's instrument—the one Dr. Leonhardt uses—is asserted by Broadbent, quoted by Landois,* to be "untrustworthy." I sincerely hope it is, for if the tracing of his own pulse, given by Dr. Leonhardt (and which he presumably regards as normal), is to be relied upon, he is either suffering from "tobacco heart" or some other form of cardiac neurosis, or he has mitral regurgitation, for a more irregular and altogether disorderly sphygmogram has rarely been exhibited to the world. An inspection of it shows that the left ventricular impulse is very unequal, and is sometimes so weak as not to affect the instrument; that the systolic wave is similarly affected; that the predicrotic wave of any one pulsation is never even approximately similar to that of any other pulsation. Either the instrument is worthless, or there is functional or organic disease. There are two other possible contingencies: One, that he was careless in the manipulation of the instrument; the other, that he is the victim of that accident at which he sneers—namely, damage in the transportation of his sphygmogram from Lincoln to New York.

Should occasion offer, I should be happy to accept Dr. Leonhardt's challenge for a sphygmographic tournament; and in the meantime make bold to advise him to change his sphygmograph for a more "trustworthy" instrument, or to use less tobacco, or to consult a specialist on diseases of the heart, or to be more careful in the manipulation of his instrument, or when he next has occasion to send a

sphygmogram to New York to send a tracing of it made on prepared paper.

As to my well meaning attempt to improve his manners, Dr. Leonhardt prefers that I should mind my own business. Therefore, with that readiness which I trust I shall always exhibit never to contend with absolute impossibilities, but to accept the inevitable with resignation, I leave that matter to the influence of the development which advancing years will doubtless effect.

SOME CAUSES AND CHARACTERISTICS OF NEURASTHENIA.*

By A. D. ROCKWELL, M.D.

WHILE very little has been added during the past few years to our knowledge of the etiology, pathology, or treatment of neurasthenia, yet it will, I think, be admitted by all whose experience entitles their opinion to weight that the disease is in most instances entirely curable, and in some cases self-curable. The enunciation and widespread diffusion of this idea I consider most important, for in neurasthenia we are dealing with a condition of mind and body that occasions more misery and paralysis of utility than many an organic and incurable disease, and because added to those wearisome and subjective symptoms of distress which only the neurasthenic himself appreciates and the physician who listens to his tale of woe, is a condition of utter hopelessness, and a resistive tendency that sometimes very materially interferes with the success of therapeutic measures. The true neurasthenic has a double burden to bear, in that, being sick and in despair, friends, relatives, and associates, in their ignorance, take little care to conceal their opinion that all these symptoms are mere figments of the imagination.

Fully aware of this incredulity and of the inability of friends to appreciate his condition, many a neurasthenic aggravates his condition by concealment and brooding, and the end is sometimes suicide. It is admittedly true that, in general, pathology and the etiology of disease are far in advance of therapeutics, but in neurasthenia we have a notable example of the reverse of this.

Our knowledge of its pathology is still conjectural and unsatisfactory, and in the study of its genesis and gradual development the most painstaking observation and analysis are still required. It is a source of satisfaction, at all events, that whatever tentative knowledge we possess in this direction does but confirm the correctness of the generally accepted methods of treatment.

In a note on Nervous Diseases in Low Races and Stages of Culture (*Science*, Dec. 16, 1892) Dr. D. G. Brinton holds that those are in error who claim that "diseases of the nervous system have greatly increased with the development of civilization." My own very positive conviction, based upon a somewhat extended experience in the treatment of neurasthenic cases, is quite the reverse of

* *A Text-book of Human Physiology.* Third American Edition. Philadelphia, 1889, p. 142.

* Read before the Section in Neurology of the New York Academy of Medicine, October 13, 1893.

this. In hospitals, in dispensaries, and among the very poor everywhere a typical case of neurasthenia is difficult to find, but among the well-to-do and the intellectual, and especially among those in the professions and in the higher walks of business life, who are in deadly earnest in the race for place and power, this peculiar impoverishment of nerve force that we call neurasthenia appears with alarming frequency. Dr. Brinton says also that civilization, so far from increasing this class of maladies, is one of the most efficient agents in reducing them in number and severity, especially when freed from religious excitement and "competitive anxieties." It is, however, these very "competitive anxieties," so intensified in this country, this worry of business and professional life, that civilization fosters and deepens. American nervousness is indeed a distinctive phrase, and the frequency with which allusion is made to it gives it, in the minds of many, a meaning apart from that ordinarily ascribed to the term. We hear very little of English, French, or German nervousness, and yet, in a large record of cases, the writer has thus far failed to detect any widely divergent lines of differentiation between the functional nervous manifestations of the different nationalities. But while the general characteristics of the nervous temperament are very much the same, whether observed in the English or German, French or American, and while the same general causes underlie each class of cases, it can not be denied that in America there are climatic conditions and business and social environments to the influence of which the nervous system is peculiarly susceptible, especially if complicated with evil habits, excesses, tobacco, alcohol, worry, or special excitements.

An American in England is frequently surprised to find that he is able to indulge in malt and spirituous liquors to an extent that he would never attempt in his own country, while the Englishman, if for any time a resident here, finds to his cost that excesses in eating and drinking impose a heavier tax upon the conservative processes of the body than in the humid atmosphere of his insular home.

A gentleman of a convivial turn who makes frequent trips to England tells me that on his pedestrian excursions through the country he is accustomed to drink malt liquors with impunity, while in this country, under the same conditions of exercise, he can take but a comparatively small amount without unpleasant results. The Englishman is less nervous than his American cousin, not because he is less abstemious in his eating and drinking, but because excesses in certain directions are less hurtful in his climate than in ours.

No more exact delineator of certain English types and habits has ever written than Anthony Trollope. His *Man about Town*, with his enormous capacity for brandy and soda, is a unique creature in his way, and quite puts to shame the comparatively mild potations of his American counterpart. With the will, perhaps, to indulge as freely as the Englishman, the American succumbs to alcoholic excesses that are relatively far less, and with symptoms that are oftener nervous than bilious or gouty. Another potent factor in the production of the so-called American nervousness, which is really nervelessness, is the hurry and worry

of business and professional life on this side of the water. My observing friend Marshall P. Wilder says that "the English have acquired the virtue of deliberation and are never in a hurry or fret; all business is conducted in a quiet, leisurely way that seems to an American like child's play, but is in dead earnest all the same. Your English banker will be found in some little building not at all like an American bank, and with very few clerks in sight. Nobody rushes breathlessly in or out, yet the amount of business transacted daily in that dingy little building is enormous."

In the older countries men plod along in the footsteps of their fathers, generation after generation, with little possibility and therefore little thought of entering a higher social grade. Here, on the contrary, no one is content to rest with the possibility ever before him of stepping higher, and the race of life is all haste and unrest. It is thus readily seen that the primary cause of the increase of neurasthenia in this country is civilization itself, with all that the term implies, with its railway, telegraph, telephone, and periodical press intensifying in ten thousand ways cerebral activity and worry. As before intimated, another important causative factor is found in the relative dryness of our atmosphere as well as in our extremes of heat and cold. Evidences of the dryness of this climate are observed in the drier and stiffer hair grown by Americans and in their leanness compared to the English and German. In the Northwest this peculiarity of climate is more positive even than in the East, as evidenced by the readiness with which meats when hung in the air are dried and preserved. It may be only a coincidence, but the writer has remarked the greater proportional number of neurasthenics coming from that portion of the country.

Then, again, no one can estimate the importance of the natural electricity of the body nor altogether analyze the part it plays in the human economy. What is an excess and what a deficiency has never been demonstrated, but we do know that dry air prevents the natural electricity of the body from being conducted away, and it is rational to believe that a constant excess of electricity in the body may in some cases so overstimulate as to excite a degree of nervousness that amounts to disease.

Fortunately, however, man has it in his power to rise superior to climate; can adapt his methods of living to the vicissitudes of climate.

The cause and cure of disease in general are very much in what we eat and drink and the way we live. If the American would cease squandering his vital forces by excesses, exercise a little common sense in what he eats and drinks, and practice the gospel of rest advocated by Herbert Spencer, he might bid defiance in great measure to climate and regain the old-fashioned constitution of his fathers.

Benedict understood this when he said that "if the Americans would learn from the Germans how to amuse themselves instead of yawning on holidays, the danger of neurasthenia would be diminished. Whoever has not learned how to play and jest easily succumbs to mental work."

All physiology and all pathology begin and end in the

cell, and it is quite as important to recognize the facts of cellular nutrition in dealing with the functional diseases of the nervous system as where its nutrition is perverted and poisoned by microbic agencies. The vitality of the cell is the important and underlying factor in health and disease, and experimental physiology, in relation to changes in nerve cells under stimulation, is already throwing some light upon the etiology and pathology of neurasthenia.

Electrical excitation of a nerve in association with a spinal ganglion is followed in a few hours not only by some diminution in the size of the nerve cells, but by a very considerable shrinkage of the nuclei of the cell capsule, and this change in the cell is found to be generally in proportion to the severity and duration of their stimulation.

It is a specially significant fact also that the cell recovers its normal activity and appearance only after long hours of rest, five hours of stimulation producing an exhaustion and change that requires twenty-four hours of rest to restore.

Associated with these actual changes in the nerve cells are chemical reactions that add a toxic element to the actual muscular and nervous expenditure of energy. What takes place in nerve cells under artificial stimulation takes place also, in all probability, in greater or less degree in the ordinary activities of daily life, and the fatigue of mind and body which follows concentrated or prolonged effort is in the same way dissipated by rest and sleep. This is what is to be normally fatigued.

Muscular activity through attendant chemical changes always yields certain noxious products that are both obstructive and destructive, and it is not alone rest and sleep that restore the normal organic tone of mind and body, but also the flow of blood which, while it deposits new material, carries away the waste products which clog and poison the system. A person may be said to be normally fatigued just so long as complete recuperation follows rest and sleep. Even where, through electrical stimulation or by effort of will, the repeated muscular contractions result in such absolute exhaustion that the muscle refuses to respond, or responds only imperfectly, to artificial stimuli or voluntary effort, it is still only normal fatigue if through disuse the muscular fibers regain in a few hours or days their usual tone. In involuntary muscular contractions there is no mental effort, and therefore no fatigue of the central nervous system, but in voluntary muscular effort there is a certain expenditure of energy that fatigues brain as well as muscle. On the other hand, severe mental labor results in a weakening of the inactive muscles—a condition supposed to be due to toxic influences following chemical changes in the brain. It is believed, and this belief is in accordance with accepted physiological principles, that both brain and muscle when exercised undergo a regressive metabolism of tissue of an oxidative character. The poisonous material thus set free acts upon the muscles through the circulation and weakens them.

If this voluntary or involuntary stimulation of muscular activity is frequently repeated to the verge of exhaustion, and until the recuperative power fails to bring back the muscular tone to its normal level, we have passed the bounds

of normal fatigue. The muscles, or the brain, if the strain has been along the line of mental effort, are now suffering from pathological fatigue, a condition in which the nutrition of the nerve cells is primarily at fault—an unbalanced condition of waste and repair; in other words, neurasthenia. The inanition and auto-intoxication of neurasthenia or pathological fatigue are direct results of those visible changes in nerve cells and the toxic products of exercise which accompany normal fatigue. Overstrain, from whatever cause, and the derangement of nutrition, initiated and determined by repeated toxic influences, must be accepted as the essential causes and pathological state of the neurasthenic condition.

113 WEST THIRTY-FOURTH STREET.

A CASE OF PUERPERAL ECLAMPSIA

AT EIGHT MONTHS AND A HALF OF PREGNANCY,
WITH REMARKS UPON THE USE OF
BUFFALO LITHIA WATER IN THE AFTER-TREATMENT.

By R. R. BALL, M. D.,

CAPTAIN AND ASSISTANT SURGEON, U. S. ARMY,
FORT TOWNSEND, WASHINGTON.

Mrs. M., a multipara, came into my hands during the latter part of April, 1890, for care during her approaching confinement, her regular physician being necessarily absent.

She was a large, fleshy woman, and inclined to take on adipose tissue rapidly. She had had some difficulty in her first confinement four years before, but since then had remained in good health. The case came into my hands at the beginning of the eighth month, the patient complaining of swelling of the feet and ankles and some headache.

I at once tested the urine and found it in about half of the usual quantity, and albumin about a fifth per cent.

She was at once placed upon the usual prophylactic measures, with strict admonition concerning diet, consisting chiefly of milk. The urine was daily tested, and, in spite of keeping the system depleted by means of cream of tartar and potassium acetate, twenty grains every six hours, for its diuretic and cathartic action, also Epsom salts, the urine remained small in quantity with albumin increasing.

Seeing these symptoms continue, the question arose as to the advisability of inducing labor at once, as the child was known to be alive.

Finally, in accordance with the conservatism of most authorities of the day, since no actual convulsion had occurred, although I anticipated an outbreak at any moment, I decided to await Nature's developments.

Just two weeks from the time I first saw the case, at eight months and a half, I was hurriedly summoned by the husband at 6 A. M., who stated that his "wife was dying."

I rushed into her room and found her in a severe convulsion. As I entered she exclaimed, "Oh, my head!" I at once injected hypodermically a quarter of a grain of morphine with one one-hundred-and-twentieth of a grain of atropine. No effect was produced except a transitory lessening of the convulsions, but they continued to come and go.

I at once summoned a brother medical officer in consultation, meanwhile attempting to control the spasms with chloroform. On his arrival we agreed that if venesection did not stop them, premature delivery would be necessary. An attempt to find the median basilic vein proved utterly futile, owing to the enormous quantity of fatty tissue lying over these

veins. Seeing this, the spasms increasing in violence and frequency, a fatal result to both mother and child was feared. Chloral, twenty-five grains, and bromide of potassium, forty grains, were now given by enema. Venesection was abandoned and Barnes's rubber dilators, beginning with the medium size, were inserted into the os uteri successively and retained about ten minutes each. These "dilators" were filled with cold water by means of an ordinary Davidson bulb syringe attached to their tubes.

In half an hour the dilatation was complete. The forceps was easily applied and a large female child was extracted. Of course, it had been destroyed by the violence of the convulsions. During this whole time the woman was wholly unconscious and remained so for thirty-six hours afterward.

Just here I may add, in speaking of venesection above, that when it was found impossible in the arm, recourse was had to four large wet cups directly over the kidneys. Ordinary glasses were used and about a pint of blood was extracted.

This undoubtedly lessened the frequency of the attacks for the time, during which time the dilatation was accomplished.

After emptying the uterus, contraction took place, so that very little blood was lost. Free action of skin was encouraged by the application of hot bottles, etc. Urine removed by catheter was small in quantity, very dark, and heavily laden with albumin—three quarters per cent.

No recurrence of the convulsions took place, though the patient remained drowsy and semi-conscious only for the next twenty-four hours. Copious antiseptic vaginal douches, very hot, were used daily thereafter for three weeks. Temperature did not exceed 100°. Diet was limited to hot milk with the free use of water. The urine was accurately tested daily as to quality and quantity. The albumin at delivery was a half per cent. with granular casts. The estimated urea in twenty-four hours for several days was only two hundred and fifty grains. As a result, uræmic symptoms continuing, the patient was put upon Buffalo lithia water *ad libitum*; no other water allowed. About three quarts were drunk daily at first. The urine increased in quantity by next day, color improved, quantity of urea increased to three hundred grains. Head symptoms improved. No medicine was given except to keep the bowels open. This lithia water was depended upon wholly in increasing quantities. At the end of six weeks the patient was in good condition and her urinary functions were almost normal. She then decided to go off for a visit to a neighboring public resort, in order to try the effect of a chalybeate water said to have proved excellent in kidney troubles.

One week's sojourn there produced such discomfort, constant headache, puffing around the ankles, and general malaise that she returned. Examination showed that the urine was only thirty-two ounces in twenty-four hours; albumin, one quarter per cent; some casts; urea, two hundred and sixty grains.

The patient was placed upon the former treatment, with immediate improvement in every way. The lithia water was gradually increased until urea showed five hundred grains in twenty-four hours, and seventy-five to eighty ounces of water passed daily.

The patient then rapidly convalesced and made a complete recovery.

The patient being of a heavy, plethoric type, I believe the chalybeate water was decidedly injurious.

The marked benefit as a result of the natural lithia water shows the power of this drug, in its natural state of solution, in dissolving the rapidly accumulating urea out of

the minute uriniferous tubules, thus removing this vital poison, always so prominently existing in these cases.

No more trying conditions ever confront the attending physician than these cases of ante-partum, intra-partum, or post-partum eclampsia. In the first two conditions we have to deal with the problem of two lives. Given the conditions of a living child, at seven to eight months and a half, with the mother showing marked symptoms of impending eclampsia, shall we procrastinate, temporize by the various means usually adopted, till finally we are forced to act after the explosion has occurred, and probably extract a still-born fetus?

In the above-reported case might I not have saved one life by interfering sooner? This child was certainly viable soon after the case came into my hands.

The discussion of Dr. Green's interesting paper on Eclampsia, in the *American Journal of Obstetrics* for July, 1893, at the meeting of the American Gynecological Society, shows a marked difference of opinion among medical men as to our capability to prevent entirely the full development of puerperal eclampsia when we have had charge of the case early.

I certainly believe with those who realize our total inability to prevent this climax, no matter how watchful we are in the early stages of many cases.

Yet the question of interference at an earlier stage than is now sanctioned by conservative obstetric methods is one which can only be decided by an analysis of the results obtained in a large number of cases subjected to the two different modes of treatment.

Of course, up to the seventh month the advisability of every conservative measure will hardly be questioned by any one.

I have seen nothing in the journals concerning the free and persistent use of this Buffalo lithia water in the very earliest stages of these cases.

I believe, if this were more generally adopted, many of them would escape the further development of the insufficient renal function.

My only reason for presenting this case is to call attention to its beneficial effects.

OOPHORECTOMY FOR THE RELIEF OF DYSMENORRHEA AND OTHER SYMPTOMS SUPPOSED TO BE DUE TO THE PRESENCE OF AN INFANTILE UTERUS.

By JOHN R. HINKSON, M. D.,

SURGEON TO THE ASTORIA HOSPITAL, LONG ISLAND CITY, N. Y.

Miss B., aged twenty-four, was seen by the writer in March, 1892. She then complained of frequent attacks of fainting and of great pain in the left iliac region, which at times became paroxysmal. She also had attacks of melancholia for which she could assign no reason, and had been troubled with insomnia for several years. She stated that menstruation commenced at fourteen years of age and occurred at intervals of three weeks, being always accompanied by great pain.

Three years ago she was ill for three weeks, and, from her statements, the writer believes that she had an attack of pelvis

peritonitis. Subsequent to this, menstruation occurred every two weeks and she was troubled with a constant pain in the left iliac region which became more severe during menstruation.

There were no abnormal physical signs in connection with the heart or lungs. Her family history was good.

She was at first treated for hysteria, and large doses of bromide of potassium were given to relieve the insomnia, but without effect. Finding that her case did not yield to medicinal treatment, the writer advised her to undergo an examination, as he believed that the cause of her trouble was due to some abnormal condition of the uterus or ovaries.

After several months she consented, and, on making an examination under chloroform, only an inch and a half of the sound could be introduced into the uterus. On abdomino-rectal examination, the finger in the rectum could be felt by the hand on the abdomen, and the body of the uterus appeared to be extremely short. The same feeling was conveyed by passing the sound into the bladder and the finger in the rectum. The cervix was well developed.

From the foregoing signs it was believed that the patient had an infantile uterus, but, taking into consideration the pain in the left iliac region and the statement of what appeared to be an attack of pelvic peritonitis occurring three years before, the writer was led to think that there might be a diseased condition of the left tube or ovary, notwithstanding that no tumor could be felt on examination.

She was advised that the only hope of relief was in an operation, to which she did not give her consent for several months, and not then till the pain became too great to endure longer.

On July 17, 1892, the patient was anesthetized and an incision three inches long made in the median line of the abdomen. On exploration, the uterus was found to be extremely anteverted, preventing the passage of the sound till it was straightened by the hand in the abdominal cavity, when it readily passed to the normal depth.

The right ovary was then examined and found to be cystic and adherent to the tip of the vermiform appendix.

The right ovary and tube were then removed, the tube being ligatured close to the uterus. During this process the cyst ruptured and some clear fluid escaped into the abdominal cavity.

On examining the left ovary, it also was found to be cystic. The tube was somewhat thickened, caused, as the writer believes, by a salpingitis occurring three years before, when she was confined to her bed for three weeks.

The left ovary and tube were removed in the same manner as the right one had been, and, all hemorrhage having been arrested, the abdominal wound was closed with interrupted sutures of silver wire and the peritoneal cavity drained with iodoform gauze. The dressing was composed of iodoform and corrosive-sublimate gauze, over which was applied a thick layer of absorbent cotton.

During the operation a sound was held in the uterus by an assistant. This very much facilitated the finding of the ovaries. After the operation the temperature fell to 96.4° and hot-water bottles were applied. In four hours the temperature rose to 101°. The patient vomited frequently for four days, and complained of considerable pain, necessitating the administration of morphine in doses of three quarters of a grain hypodermically.

On the day following the operation the dressing, which was quite moist, was changed. There was no suppuration or any offensive odor from the wound. The temperature was 101.6° and the pulse 110. There was a sanious discharge from the uterus. This continued for two weeks.

On July 21st the bowels were moved with an enema, the dressing was changed, and the gauze employed for drainage was removed. The appearance of the wound was perfectly healthy. Temperature, 100°; pulse, 110.

On July 26th the dressing was again changed and the sutures were removed.

Suppuration was discovered at the site of drainage and the two lower stitch holes on the left side. Temperature, 100.4°; pulse, 100. After this date the dressing was changed and the wound irrigated with hydrogen peroxide every day for the five succeeding days.

During this time the temperature ranged from 99° to 101°, and the pulse from 75 to 90. After this the dressing was changed every second day, and the pulse and temperature became normal on August 7th.

A suppurating sinus remained at the lower extremity of the wound where the drainage had been employed, and did not close till September 1st.

At this writing, five months later, the patient weighs one hundred and seventeen pounds—three pounds in excess of her weight the day previous to the operation. She sleeps well and is entirely free from pain. There has been no recurrence of menstruation.

SOME CONSIDERATIONS

RESPECTING EXAMINATIONS AND TREATMENT IN HETEROPHORIA.*

By GEORGE T. STEVENS, M.D.,

NEW YORK.

PERHAPS I may be pardoned, in consideration of the subject assigned for this day's discussion, if I indulge in some satisfaction when I contrast the sentiments prevailing among oculists at the present time regarding that subject with those which prevailed only a few years since.

At the meeting of the Ninth International Medical Congress, held in this city in 1887, just six years ago, I read before this section, the same gentleman presiding who now occupies the chair, a paper with the title *Some Important Problems respecting Insufficiencies of the Ocular Muscles*.

Directly after the publication of this title in the medical journals I was violently criticised in some of the leading periodicals, not for the special views contained in that paper, for it had not yet appeared in print, but for the presumption and folly of suggesting that there were any problems regarding what were then known as insufficiencies of the ocular muscles. The public was emphatically informed in effect that all the problems in this department of science had long ago been solved, and that there was nothing more for me to suggest or for the profession to consider.

The writers undoubtedly voiced the prevailing sentiment of the profession at the time; otherwise, had they expressed only their individual views, there would be no occasion for recurring to the incident here.

To-day, six years later, this section of this great congress assigns one entire day to the study of the very problems which, six years ago, we were told had already reached a final solution.

When, at the request of the president of this section, I

* Read before the Ophthalmological Section of the First Pan-American Medical Congress.

consented to participate in this discussion, I was in doubt what I could best offer for your consideration. In reply to my appeals to the president to tell me what part of the subject he wished me to present, he gave me the whole field to discuss, but he did not give me more than one day in which to do it. At the last hour I have determined to speak not of new things, but to direct your attention to some things of which I have already spoken, but placing them in a light which may possibly encourage some inquirer. If I shall be able to accomplish that I shall be glad that I have chosen this course.

In the first place, I venture some words in regard to examinations for heterophoria. Perhaps the suggestions that I am to make are needless repetitions, yet I am led to the belief, by examining much of the current literature of the subject, that it may not be out of place to call attention to the fact that deductions from many points of view and much careful and logical thinking are essential elements in the making of these investigations.

It is not, in the brief time allotted to me, possible to go into any details of examinations, but permit me to suggest an order and some important points which may be brought out by an orderly examination.

The facial expression of our patients will often give us strong hints of what we may expect to find. Indeed, these expressions are so well marked in their relations to the condition of the ocular muscles that one who has had considerable observation and who is withal a close observer will rarely fail to make a general, though tentative, diagnosis of his case without the aid of his instruments. Of course this is not a working diagnosis, but it is a valuable aid to that which is to follow and often serves to direct the attention to slight inconsistencies in the instrumental examinations which otherwise might escape notice. A glance at the eyes themselves and at their movements prepares us, after we have learned what is necessary of their refractive condition, for the more exact examination.

First in order, after considering well the facial expressions and the movements, the phorometer is brought into use and its results are recorded. If other instruments than the phorometer are employed for the purpose of indicating the manifest heterophoric tendencies either by induced diplopia or by contrasting images, let me repeat what I have already said elsewhere—that no instrument of this class which is held near the eyes, or the correcting prism of which is brought close to the eyes, can be relied upon for such exact examinations as should be obtained if we are to make a critical study of our case. Some of the instruments which are in common use will give us false information to the extent of many degrees. The tendency to overcome a deviation of the images from the vertical or the horizontal lines is similar if not as strong as the instinct to unite images by overcoming prisms. If the phorometer is placed at the distance of from four to six inches in front of the eyes, these adjustments, which are so naturally made, are either entirely or in large measure neutralized.

In whatever way we ascertain the phorometric measurements, we must bear in mind the important fact that we have arrived at only a single stage of the examination and

that other classes of facts must enter into the question of interpretation of the ocular adjustments. We must ascertain the abducting and the sursumducting ability, and perhaps also the adducting ability. We are to observe the action of each eye when temporarily excluded from fixation and when it returns to fixation.

If, assuming the standard of the abduction to be eight degrees at twenty feet—a standard adopted by myself many years ago and which experience has shown to be a correct one—we find that it corresponds to the record of the phorometer, and if the sursumduction right and left also corresponds to the indication of the phorometer, we may fairly assume that we have an uncomplicated case in which the reading of the phorometer may be taken as an index of the actual condition so far as the kind of tendency is concerned. But if, as often happens, the records of the various tests—for example, the phorometer, the abducting ability, the deviation in exclusion—are not in harmony, we are to search for the cause of this want of correspondence. For example, if by the phorometer we find esophoria two degrees and abduction six degrees, or even five degrees, with equal sursumduction and no hyperphoria, we arrive at the conclusion that we are dealing with a case of simple esophoria, two degrees of which are now manifest. On the other hand, should we find esophoria of two degrees with abduction of ten degrees, or exophoria of two degrees with abduction of six degrees, we may at once conclude that we have a complicated case, even although there is no manifest hyperphoria, and one which must demand the most careful attention before any radical measure of treatment is adopted.

There are so many forms of these contradictory indications that I can only allude to them as a class as intimations for the most careful study of the cases and as warnings that we must in no case assume that one class of testing tells us the whole truth. We should note the facial-expression test by the phorometer, try the ability to overcome prisms, examine carefully the rotating ability of each muscle, and the action of one or other eye when excluded from fixation. These and often many other points are to constitute elements in our examination.

And here let me add that if we are at the present stage of knowledge of this subject to publish our case, the bare statement that the patient had an abduction of only five degrees, or that the phorometer showed a certain degree and form of heterophoria, will not suffice for critical readers. Such readers must know all about that case. They have seen too many instances in which an abduction of twelve degrees may have been associated with an actual converging squint to accept a bare statement of the extent of abduction and adduction or the registration of the phorometer as having any scientific value. Moreover, such a statement leaves in the mind of the critical reader the impression that the writer had not himself ascertained the remaining facts necessary to a just conclusion in regard to the nature of his case.

A single word more regarding these examinations. Contrary to the general impression and contrary to my own teachings of many years ago, the correction of the refract-

ive anomalies by glasses during an examination of this kind is not only in the vast majority of cases unnecessary but positively detrimental, as the glasses themselves often lead to error and their absence does not, as a rule, influence the muscular conditions.

And now that we have in the few minutes gone over the examinations in heterophoria—a subject which for its proper consideration would require long-continued and patient study—let us as briefly sketch an outline of some of the methods for the management of the defects which we may have discovered. Let no one suppose that this sketch can be in any degree more than suggestive.

One of the first of the elements in the management of these cases is patience. The oculist who imagines that he can measure and correct his cases of heterophoria in an offhand manner has not reached an understanding of the first principles of the subject. A case which at first appears quite simple and easy to handle may prove to be one which for its best correction may demand the exercise of great skill and of unwearied patience during many months.

We can not know when we begin the treatment of a case of heterophoria the full meaning of the indications which we then discover. One who thinks that he has found an instrument which will reveal latent heterophoria is surely laboring under a misapprehension. As we go on in the treatment of these cases new difficulties may arise and new efforts may be demanded. This is no reason for not beginning the work, and less for abandoning it before completion.

I have sometimes illustrated these progressive difficulties by recalling the experience of one who climbs a mountain. He sees before him a height which appears to him the summit which is to reward him for his effort, but when he reaches it he sees before him another even higher than the one which he has surmounted. He ascends higher, and when at length he attains to the second height the real summit is still above him. Is he therefore to say, "There is no end of this, and one might climb indefinitely without finding the summit?"

There is a summit, and one may reach it if he has the needed strength and courage.

I am sometimes asked by my colleagues if there is no end to the treatment of these cases. Does not the condition which has been apparently removed return? Must the treatment not continue indefinitely?

The heterophoric condition which has been in any measure properly corrected does not return, but that part of the original defect which was at one time latent may at a subsequent time become manifest.

There is as surely a limit to this work as there is a final summit to the mountain, and when one reaches that limit he has an infinitely greater satisfaction than he who finally gazes upon the stretch of hills and plains and lakes from the elevation which he has earned.

Many who do not care to take the trouble to climb decline to accept the reports of those who do, and many an eminent man who has lingered about the foot-hills of this work is incredulous because he can not obtain the same

grand view that has been described by some one who has gone beyond.

An essential to success in this work must be a thorough knowledge of the principles governing the tensions of the muscles with which we work.

Instruments can not know these principles. They are only to be learned by long and patient research on the part of the oculist.

But what immediate steps are we to take for the relief of our patient with heterophoria?

We may give him prisms. Will they help? Sometimes, and to a very limited extent. In the large majority of cases they will serve little purpose, or perhaps produce decided annoyance. In the cases in which they afford relief, that relief is in no sense the effectual degree of comfort and the absence of reflex trouble which may be expected from the more radical relief of abolishing the heterophoric condition.

Then we may give to the muscles the gymnastic exercise which may be accomplished by the overcoming of prisms.

That good may be accomplished in this way I have long ago demonstrated. The fact remains that the method is but tentative. The anomalous conditions remain, and the unpleasant symptoms will probably return. A vast experience with these two methods enables me, I believe, to speak of them with some degree of authority, and I do not hesitate to say that, while they have much value to recommend them, and while no one can afford to overlook them, they fall far short of the more rational measures of actual adjustments by means of equalizing the tensions in such a way as to establish practical orthophoria.

We may accomplish this by graduated tenotomies and tendon contractions.

Are we then to operate for all cases of heterophoria? By no means. The surroundings of the patient, his methods of work, the importance of the case, and many such considerations must enter into the question of treatment. The best judgment of the experienced surgeon is here in demand.

In most cases, however, in which important reflex disturbances are the result of heterophoria we shall find operative measures imperative.

How are we to operate? I must reply first in the negative. How are we not to operate? We are not to operate by the methods described in the text-books which I have seen. Indeed, if I may be permitted to diverge from our strict line of thought in a single sentence, I will add, we should not for any condition of heterophoria, strabismus, or paralysis perform any tenotomy after the manner thus described. We should never operate in such a manner as to disable our muscle in its function of rotating the eye.

We are told of tenotomies which are so far in excess as, after the relaxation, for example, of a single external rectus, to leave the patient with homonymous diplopia for some months. It is true that single vision may in some instances return and that even a condition of exophoria may succeed, but if the ability to rotate that eye well to

the temple has been lost at the moment of the operation, it will never return without a readjustment of its insertion. Let me impress this important fact upon the mind of every one who operates for heterophoria that, whatever may happen in regard to phorometric indications, the rotation of an eye after tenotomy does not undergo any very important change, and that we can not at the time of the operation disable this function in the expectation that the tendon will readjust itself. We should never attempt a complete and final correction on a single lateral muscle. If we have even a low degree of heterophoria, we should proceed on the assumption that when we have finished the work we shall have relaxed the lateral muscle of one eye exactly, or as nearly exactly as we are able to determine, as much as we have that of the other. There is an important consideration, too often overlooked in operations for hyperphoria and especially for hypertropia, that the gaze of the great majority of our patients must be habitually directed downward. Hence a tenotomy of an inferior rectus is, as a rule, to be avoided, unless there are positive indications for selecting that muscle.*

Before any operation, even in well-defined cases, more than one, and usually many examinations should be made. Prismatic glasses, usually less than a nominal correction of the manifest heterophoria, should be given and the patient should be charged to use them continuously during waking hours. From time to time, during the use of these glasses, examinations may indicate a greater degree of defect than was at first found and the prisms may be strengthened. The use of temporary prisms which are kept by the oculist, as suggested by me some years ago, has now become somewhat general. After a time, varying from a few days to a few weeks, we have either found such a degree of heterophoria as would be all that we might reasonably expect to relieve by a single operation without risking a restriction of the rotating power of the muscle to be operated upon, or there has been a halt in the further manifestation of heterophoria. We may now proceed with our operation if such a course is chosen. I have already more than once described this operation, but I will venture to do so again in order to introduce some details concerning which inquiries have often been made.

Let us suppose the operation to be done for esophoria, and that we have determined to do a graduated tenotomy of the right internal rectus.

FIG. 1.

• The speculum being in place, the patient directs both eyes well to the right. The surgeon takes with his fine forceps (Fig. 1) a minute fold of conjunctiva at the center of the

insertion of the tendon. Drawing the little fold of conjunctiva slightly away from the eyeball with the extreme points of his tenotomy scissors (Fig. 2), he snips the fold trans-

FIG. 2.

versely so that an opening about half a millimetre in extent is made through the membrane. Now the forceps, the points being closed, is pressed into the little opening and slightly backward, when the points are permitted to spring apart, after which they are again closed, this time holding a small fold of the tendon just behind the insertion. This little fold of tendon being put on the stretch, the fine-pointed scissors, by little snips, dissects the tendon from the eyeball between the layers of the capsule (which should remain intact) toward one border of the insertion. The sense of feeling of the fingers against the rings of the scissors will, in the hands of one skilled in this operation, inform him of his approach to the border and warn him against its destruction. In extreme cases, like strabismus, the surgeon may determine to continue his section through the border, leaving uninjured, as far as possible, both the anterior and posterior lamellæ of the capsule, as well as the expansion at each border, to hold the muscle in relation to the eye. Turning the scissors then in the direction of the other border, this portion is dissected with equal care.

With as little delay as possible the patient is placed in the examination chair, and the test by the phorometer and by prisms is made. It is safe in very moderate cases, by the first operation, to carry the correction to 0° and the abduction to 10° or 11°, for at the moment there is likely to be a greater nervous relaxation than will be found an hour or more later, and it may be reasonably expected that within a few days there will still be a manifest esophoria sufficient, especially if the temporary prisms are again brought into use, to permit of a relaxation of the corresponding muscle of the left eye equal to that now being done on the right. Such an extent of relaxation may, however, be contraindicated should it appear that the nasal rotation, which should be tested before the patient leaves the operating chair, is in danger of being unduly restricted.

Perhaps we find that esophoria is still manifest, and that the rotation is still abundant. The patient returns to the operating chair, when the surgeon, introducing the slender, blunt hook (Fig. 3), feels for the point to which the sec-

FIG. 3.

tion has been made, either above or below. He soon finds, if he is expert, whether the section has been carried far enough in that particular direction, and, if so, he searches at the other extremity. If he now finds room for carrying the section farther, he, using the slender hook as a guide, or returning to his forceps, increases the effect of the tenotomy

* Should a correction for a considerable degree of hyperphoria or of hypertropia be required, the correction should, of course, be divided between the superior rectus of one eye and the inferior rectus of the other. The statement above applies to cases especially in which only a moderate relaxation is required. Considerable restriction of the upward rotation is to be avoided on the one hand and the turning of the axis of the eyes upward on the other.

by carefully executed snips of the scissors, and after an examination this process may be renewed if required.

If by chance we find that we have erred in judgment and have gained an exophoria with abduction exceeding 11° , we must at once introduce at the exact center of the free end of the tendon a very delicate suture, carrying it through the cut edge of the conjunctiva at the corneal side. There is an occasional exception to this rule, in which, if we permit the patient to wait for an hour or less, the exophoria and excessive abduction may disappear. We make this suture to include as little as possible of either tissue, and then draw it with great care until we have overcome the exophoria, as shown by the phorometer, when the knot may be made fast. This process, although sometimes demanded in the practice of the most skillful, is always unfortunate. Those who tell us that we should cut the tendon across and then introduce the suture are, I am sure, in error.

Should it be found on the following day that the result is not what could be desired, the suture may be renewed, or by removal an increased effect of the original operation may be obtained.

There are conditions which render it almost imperative in a certain small proportion of cases to make adjustments in lateral tendencies which, although not more than nominally correct at the time of making, are such that the experienced surgeon feels almost sure that when he is better able to adjust for a supposed hyperphoric condition, will at length prove overcorrections. Such overcorrections when they become manifest must be restored to equilibrium. Now, it should be an axiom, a rule never to be forgotten, that we have no right in any case to weaken a muscle because we or some one else has weakened the opponent of that muscle. For example, if, as the result of a tenotomy of the internus of one eye, we have an exophoria of even as little as a single degree, it is inexcusable to cut the externus in order to relax that muscle equally with the excess of relaxation of the other.

Let me repeat, we are not to correct an overcorrection by a new tenotomy.

In all such overcorrections we should resort to tendon shortening or advancement of that tendon which has been too freely relaxed. If the original tenotomy has been done in the manner I have just described, there will be little difficulty in performing a correction which shall leave no cicatricial bands to interfere with the freest action of the muscle.

We begin in this operation, as in that for tenotomy, by making a transverse slit of half a millimetre in extent over the point of insertion of the tendon. Then, lifting the border of the conjunctiva nearest the cornea by the fine forceps, a little pocket is made by the points of the scissors or the lance probe (Fig. 4), extending under the conjunctiva

tially, as the case may be. If it is entirely dissected, then, by means of the scissors point acting as a probe or by means of the lance probe, the tendon should be absolutely freed from any attachment to the surrounding tissues. The fine tendon crotchet (Fig. 5) now catches it at the center and

FIG. 5.

a little behind the section and draws it forward, or, if the hook proves to be ineffectual to hold it during the next stages of the operation, the fine fixation forceps with catch may be used (Fig. 6). The tendon is drawn forward through the little conjunctival opening, when one of the needles from

FIG. 6.

a thread of silk armed at each end with a needle is passed through the central part from a half to a full millimetre or even more behind the cut extremity. Bringing the needle forward until the two extremities of this thread are about equal in length, an assistant carries the lance probe into the pocket already made, and one of the needles, passing by the side of this probe, which acts as a guide, is made to penetrate the conjunctiva at the extreme end of the pocket and the thread is drawn through. The other needle and its thread are managed in like manner, the second needle penetrating a little to one side of the first in order to allow between the two threads a little bridge of tissue. Now, the assistant holding the conjunctiva at the border of the wound by means of fine forceps, the surgeon draws upon the ends of the thread, forcing the cut end of the tendon into the little pocket, and when he has thus advanced it to his satisfaction he fastens the threads by tying them across the little bridge.

No cover and no especial care is required beyond that needed for perfect cleanliness, and on the third or fourth day the suture may be removed. The greatest danger in these cases arises from the use by the patient of a soiled handkerchief with which he rubs the eye. Against this danger the strictest injunctions are to be enforced.

This operation, with such modifications as may be required, I have performed during the past five or six years in some hundreds of cases, where advancements have been required, and it has been witnessed by some scores of my colleagues.

33 WEST THIRTY-THIRD STREET.

THE MECHANICAL TREATMENT OF OSTEITIS OF THE KNEE.*

By HENRY LING TAYLOR, M.D.

THE term osteitis of the knee, or "white swelling," is used to designate a tubercular, purulent, or mixed process which usually begins in an adjacent epiphysis or in the

* Read by title before the American Orthopaedic Association at its seventh annual meeting.

FIG. 4.

more or less toward the cornea in proportion to the greater or less effect which we propose to induce. The pocket having been made, the forceps seize the central portion of the tendon and it is dissected from the eyeball entirely or par-

synovial membrane, and, if unchecked, finally involves most of the joint structures.

Some of the classical symptoms of inflammation—namely, pain, heat, redness, swelling, and impaired function—are less marked in chronic than in acute affections; the first three may be entirely absent at certain stages or in certain types of chronic knee disease. Tenderness, especially circumscribed tenderness, is more constant and of more significance as an indication of osseous involvement, as recently pointed out by Senn; but in all stages of joint disease, where the synovial membrane is irritated, the tonicity of the muscles acting upon the joint is of more importance as an indication of the condition of the joint in difficult or doubtful cases than all the other symptoms put together, and always calls for critical examination. Atrophy of the limb above and below the joint is also a constant symptom. Whatever the irritant or pathological process, if continued and involving the joint, certain symptoms regularly appear as the result of reflex spasm acting upon the joint under the mechanical conditions present; and certain deformities regularly accompany chronic inflammation of the knee, as the expression of a tendency to a dynamical equilibrium of the different forces acting upon the joint. The thigh muscles are stimulated through reflected joint irritation, and the flexors being more advantageously placed than the extensors, the knee becomes gradually more and more flexed; from preponderance of the biceps at the outer side of the knee, and from its more advantageous leverage through its insertion into the head of the fibula, the tibia is rotated out and abducted; and as the posterior group of muscles pull the head of the tibia directly backward when the knee is semiflexed, the head of the tibia undergoes the characteristic subluxation backward, there being no adequate force to oppose it—that is to say, the mechanical arrangement of the joint and its muscles favors flexion, eversion, abduction, and subluxation. This is also seen after poliomyelitis, where similar deformities are more gradually produced without spasm.

Under the reflected stimulus of an irritated joint, however, the muscles tend to produce by their exaggerated but irregular tonicity a position of less discomfort—that is, of less tension and less irritation. Volition has little to do with it. If irritation is intense, even in the semiflexed position, flexion may become excessive without relief, and in most untreated cases, where the joint irritation is considerable and long continued, eversion and subluxation and often abduction are gradually produced, clearly unaided and unhindered by volition.

The knee, if considerably damaged and left to itself, gradually becomes more or less fixed in this flexed, everted, abducted, and subluxated position, from thickening of the ligaments, adhesions, and the adaptations of the hard and soft structures to the deformed position. In certain cases bony ankylosis may finally occur, or the patient may succumb to a complicating tuberculosis, local or general, septicæmia or its sequelæ, or exhaustion. It is also true that milder grades of the affection do occur, which get well with a more or less useful joint under comparatively simple treatment.

The indications for treatment in this affection, and also in chronic synovitis of the knee, are local and general.

The general indication for treatment is to improve the nutrition of the patient, and thus insure a blood supply of good quality to the diseased area to favor the reparative process. The principal means to this end are an abundant supply of fresh air, a nourishing diet, the relief of local irritation, and the correction of complicating disorders. Local mechanical treatment is the mainstay in meeting the general indication, since it relieves the organism of the depressing drag of a constant irritation, whether painful or not, and permits the patient to pass much of the time in the open air. These two elements are powerful aids in stimulating appetite and cheerfulness and in banishing sleeplessness and nervous irritability. One of the most gratifying results of proper mechanical treatment is the marked and speedy gain in general health and vigor.

The local indications for treatment are to provide conditions favoring the process of repair at the site of disease, to prevent or correct deformity, and to restore so far as possible the functions of the joint. They vary according to the stage and grade of the disease and the special features presented, and are met by mechanically protecting the joint from pressure and internal and external traumatism, thus favoring a more normal local circulation; by gradual correction of the deformity, and later by the protected use of the muscles and joint. In the stage of irritation and disintegration the local circulation is defective and local nutrition is impaired from distention or from articular pressure. The sore joint surfaces are jammed together by abnormal muscular spasm; this increases irritation and local necrosis, multiplies the evil effect of movement and jar, and is unfavorable to the healing process. The mechanical indication is to keep the joint surfaces from pressing and rubbing against each other, in order to allay muscular spasm and prevent injury. This is done by applying mechanical counter extension and fixation to the joint, the patient being kept in bed until the acute symptoms subside. Rest in bed for a time is necessary where much irritation exists, but does not alone meet the local indications. Mechanical counter-extension must be added to relieve the pressure upon the tender joint surfaces. This counter extension must be applied with precision in the lines of present deformity or so near them as to be perfectly comfortable. Indeed, if pain is present and rest is disturbed, these symptoms are regularly and promptly relieved by proper counter extension; the relief from pain is often instantaneous, as in the following case:

A young man who had been in such pain for months from an exacerbation of synovial inflammation that he had been kept under morphine, and that his physician and friends had considered it impossible to move him, was finally brought to New York. Fixation alone had been of small avail, but he breathed a sigh of relief the moment the straps of the counter-extension apparatus were tightened, and he remained free from suffering from that time, with coincident subsidence of the inflammation.

The joint then must be put to rest in the strictest sense until all irritation has disappeared, the patient's health has

improved, and we have reason to believe that the healing process is inaugurated. The time spent in bed will be from four to eight weeks, but the splint is applied at once, and worn continuously day and night. When the patient is recumbent a weight of four to eight pounds is attached to the apparatus, which may be so contrived that most of the varying indications at different stages of the disease can be met and the joint controlled at the will of the operator.

The apparatus preferred by the writer consists essentially of Dows's supporting splint, devised by Dr. C. Fayette Taylor, to which are added a snap joint at the knee and a steel circle for fixing or changing the angle of flexion.

By means of the apparatus the knee is supported laterally and fixed at the angle of choice, which must be such that no leverage is exerted, and counter-extension is secured by a perineal strap and by adhesive plasters applied to the leg below the knee. A ratchet or screw extension is not required, as moderate force only is necessary for the knee, much less than for the hip, where the muscles are more powerful, and is obtained by traction on the strap attached to the plaster and secured by a buckle. The leg bar of the apparatus must be rotated to nearly correspond with the eversion, so that no twisting force is exerted on the knee. If the fixation is in the proper position without leverage or torsion, and the traction is properly applied, muscular spasm will relax by degrees, and a corresponding correction should be made in the apparatus. The restoration of local conditions favorable to healing is one indication, and the correction of the deformity another, but the two should proceed coincidently. Allaying muscular spasm by constant traction with fixation and, when necessary, recum-

bency, permits a gradual and painless rectification of the deformity in a large number of cases, and as rectification of the deformity progresses, the mechanical conditions for counter-extension and fixation are more readily and perfectly fulfilled, and in many instances the joint is put into a condition more favorable for healing.

Many forms of apparatus are used to meet special indications, but the one we have found most generally useful and most readily adjusted to meet varying indications is the lock-joint supporting and protective apparatus already mentioned (Fig. 1). It is made of steel properly lined with leather, and consists of two bars with an accurate and substantial joint at the knee, which, however, is

FIG. 1.

fixed by a spring during the first stage of the treatment. To the bars are riveted slightly concave steel thigh and leg plates, fitting accurately the external aspect of the limb. The

lower bar, made of two overlapping pieces to allow of adjustment, reaches slightly below the foot and is provided at the lower end with a slip-joint, fitting into an L-shaped steel plate in the shoe, which may be applied and removed without disturbing the brace; the length of the brace is such that considerable space is left between the heel of the foot and the sole of the shoe (Fig. 2). To the leg-plate is riveted a leather legging which surrounds the leg, lacing up in front. At the upper end of the apparatus steel horns carry the perineal strap, an anterior thigh-plate keeps the apparatus from falling backward, and a knee-plate carried by a curved, protected steel band and fitted above the inner side of the knee prevents lateral motion. A strap above the popliteal space and a buckle on the leg-plate to receive the adhesive plaster webbing completes the apparatus, which should be made of superior materials and workmanship to insure the perfect adaptation and solidity which alone can give the comfort and instinctive confidence necessary to successful management. A slight elasticity or "give" in the apparatus will set the irritated muscles on guard and check progress. A three- or five-tailed adhesive plaster (Fig. 3)* is applied to the outer side of the leg below the knee before the apparatus is put on. If the knee is sore and inflamed, the patient will still lie in bed after the application of the apparatus to insure perfect rest and absence from jar. When the patient can be moved comfortably with the brace, and inflammatory action seems to be regressive, the patient may be allowed to sit up or walk about on crutches, allowing the affected limb to hang. When healing has progressed still further, the patient may walk between two crutches and finally with a cane, taking the weight upon the perineal strap of the apparatus, which is "itself an ever-present crutch for the purpose of supporting the weight of the body during locomotion."†

FIG. 2.

When so far advanced toward recovery that inflammation is absent, the knee may be slightly bent when seated by releasing the catch, which, owing to the peculiar construction of the release, can easily be done through the clothing (Fig. 4). Later still the catch may be held open by inserting a rubber or wooden wedge beneath the spring, and the patient may be allowed to use the knee with motion, which may be

FIG. 3.

* A Ready Method for Counter-extension at the Knee. By the writer. *Boston Medical and Surgical Journal*, October 16, 1890.

confined within selected limits by placing steel stops on the joint disc, the delicate, newly-healed joint structures being protected from friction and superincumbent

FIG. 4.

weight and from lateral strain by the apparatus with its load-bearing perineal strap. Preparatory to discontinuing the use of the apparatus, the weight of the body may by degrees be allowed to rest upon the knee by lengthening the perineal strap and by shortening the leg-bar, so that the heel is allowed to approach or touch the sole of the shoe. It is believed that the gradual introduction of the muscles and joint to their natural function is not only safer than an abrupt change from fixation to walking without support,

but that the prescribed graduated use of the muscles and joint without harmful friction, in the absence of inflammation, is itself a remedial measure of high value in the recovering stage, through its effect in improving the circulation and nutrition of the parts, thus favoring their more perfect restoration.

Nothing could be further from the purpose of this paper than to advocate any particular form of apparatus as pre-eminently excellent in the treatment of osteitis of the knee; rather the intention has been to emphasize the varying indications presented by the disease in its different stages, which may be met in different ways once the principle of continued positive protection with the allaying of local irritation is recognized. The elements of protection vary with the different stages of the disease. The continued use of protective apparatus, properly manipulated, not only fulfills the local indication for enforced rest to the joint, but does so with a minimum of confinement, enabling the patient at an early stage of the treatment to move about and get an abundance of pure air, than which no general measure is more important. The knee is practically put to bed while the patient is up and moving about. "In a word, to be master of the situation, and to be ready and able to respond to all indications, separately or at the same time, constitute the problem of the mechanical treatment"* of chronic disease of the knee joint.

201 WEST FIFTY-FOURTH STREET.

Professor Samuel Pozzi, of Paris, met a number of New York and Brooklyn physicians at dinner at Dr. John Byrne's house in Brooklyn on Thursday evening, the 16th inst.

* *Loc. cit.*

A NEW APPARATUS

FOR OBTAINING THE CONTENTS OF THE STOMACH
FOR DIAGNOSTIC PURPOSES.

By M. GROSS, M. D.

THE general and well-known methods for procuring the contents of the stomach are, firstly, *the method of expression*; secondly, *the method by aspiration*.

By the first method the patient is told, after introduction of the stomach tube, to press out—in this way, through the simultaneous contraction of the diaphragm and the abdominal muscles, causing the contents of the stomach to be forced through the tube. This method, introduced by Ewald and Boas, is in truth the most prevalent. But Ewald himself mentions that a small percentage of the patients called upon to press out generally make but short, spasmodic movements of expiration. In such cases we must apply the method of aspiration. By the second method the contents of the stomach are obtained, after introduction of the stomach tube, by aspiration. Nevertheless, it has often been a matter of consideration whether or not by any less annoying and disagreeable method we could gain possession of the contents of the stomach.

Among others, small sponges or olive shaped receptacles attached to silk threads have been allowed to be swallowed, and upon the withdrawal of these the liquid thus obtained been subjected to an examination. These methods give uncertain results, withdrawing too small an amount of fluid to allow us to form a correct and definite opinion of the macroscopical and microscopical appearances and the chemical constituents of the contents of the stomach.

Even if Ewald, Leube, and others regard the introduction of the stomach tube hardly as an annoying and disagreeable procedure, nevertheless we must admit that, in spite of the application of cocaine and a well-practiced hand, the patient must endure, on the introduction of the tube and during its stay in the esophagus, much discomfort and disagreeable sensations. It is not a matter of indifference whether a wide and hard tube causes a sense of suffocation and vomiting, inasmuch as under these circumstances the least movement will produce these disagreeable symptoms. Only he who himself has had the tube introduced can judge of this "pleasant" situation. With the introduction of my stomach tube I have succeeded in reducing these unpleasant symptoms to a minimum.

The principle is as follows: A tube small in caliber and soft in texture (a Nélaton's catheter for *lavage* in children) is swallowed by the patient, and thus the contents of the stomach are obtained by aspiration. The choking and vomiting sensations, on account of the thinness and softness of the tube, are absent.

The apparatus may be divided into three parts—a stomach part, a middle part, and an end piece.

The stomach part (A), the part to be introduced into the stomach, may consist of a long, thin Nélaton catheter with one opening at its proximal extremity, or it may simply possess an olive-shaped end, the latter of which I prefer, inasmuch as it may the more readily be swallowed, and on that account I myself make use of it almost exclusively.

This olive extremity is composed of hard rubber and covered entirely by the rubber tube. The middle piece (B) represents an eccentric glass bulb for the purpose of collecting the stomach contents, and connected with the bulb a manometer for determining the changes of pressure in the tube. The end piece (C) of the tube is made up of a modified Politzer bag, or it may consist simply of a mouth piece (D), in which case the physician himself aspirates.

At the introduction of the tube the olive is pushed back until it reaches the posterior wall of the pharynx and the patient is told to swallow. At the well-known spot where the pharynx is continued into the œsophagus the olive causes in some cases a slight effort of deglutition, and then glides down the œsophagus into the stomach. I have often tried this

myself, and with the tube introduced been able to breathe quietly, speak without effort, and by aspirating at the mouth piece I bring forth the contents of my stomach.

In cases of very pronounced contractures of the muscles at the above-named spot, and the consequent difficult passage of the olive, I withdraw the tube and begin over again with the certainty of a better result.

An objection raised against the aspiration method is the likelihood of the mucous membrane of the stomach becoming hemmed into the opening of the tube; and it is known as a fact that part of the mucous membrane has been torn off. In order to avoid this mishap I never aspirate before the olive has dipped into the contents of the stomach, which I ascertain by blowing into the tube and then hearing a noise such as is produced by the blowing of air through fluid. Furthermore, I aspirate myself, because I can then easily ascertain the moment when the opening of the tube becomes clogged.

In the majority of cases the Politzer bag is used for aspiration; the manometer will indicate by its changes of pressure whether or not some obstruction, such as particles of food or mucous membrane, is present, and thus caution us. Should obstruction occur, I blow into the tube, ask the patient to swallow, or withdraw the tube slightly, when the obstruction will disappear.

In conclusion, let me state that this apparatus* may also be used for inflating the stomach, but only to a certain extent, as the air returns through the cardiac extremity of the stomach on account of the small size of the tube.

This apparatus can likewise be used as a tube for washing out the stomach.

* The experimental work was performed by Mr. Otto Kloppe, New York city. In case of wearing out of the stomach piece the physician himself can apply the tube again by cutting off the tube just behind the olive and drawing back the tube piece that covered the olive; the mechanism of the fastening of the tube will then easily appear.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 18, 1893.

THE REPORT OF THE HEALTH OFFICER OF THE PORT
OF NEW YORK FOR THE YEAR 1892.

In this recently published report Dr. Jenkins explains its delay as due to the pressure of official duties, and gives a detailed statement of the condition of the establishment when he was appointed health officer. During the year he inspected 5,383 vessels from foreign ports and 1,952 from domestic ports, for which service the former paid \$24,022.50 and the latter \$3,166. But these were not the only sources of revenue, for fumigation, for which \$8,545 was received, night-boarding, transportation, vaccination, and the medical inspection of immigrants raised the total receipts to \$48,466.47—a sum more than sufficient to meet the expenses of the service and have a balance of some \$1,700.

These figures are mentioned to refute, in the first place, an impression that the health officer of the port of New York receives in salary and perquisites more than the President of the United States, and in the second place to show the heavy tax that is imposed upon the commerce of this city to protect the health of the country. The number of immigrants inspected was 388,186.

There is a table that shows the number of passengers brought by each steamship line and the number of developed cases of small-pox found among the passengers of each line on arrival at this port.

There is an elaborate history of the cholera epidemic among the steamship passengers during 1892. We think Dr. Jenkins is correct in declining all responsibility for the purchase of Fire Island, and in his refusal to transfer people to Camp Low. Both these quarantine establishments were the creations of panic, and their institution was a needless waste of money. If the medical profession has learned anything at all, it has been for several years cognizant of the fact that cholera is not a miasm and that it must be introduced into the system by food or drink. Such being the case, a steamship is an ideal place for the segregation of people that have been exposed to cholera infection, because the food supply and the water supply are under absolute control, disinfection of the inhabited parts of the vessel may be rapidly accomplished, and supervision of the passengers may be constantly carried on by the physician. The best thing the State of New York and the United States can do with Fire Island and Camp Low, respectively, is to dispose of them and thus get rid of them. They are vestiges of that fifteenth-century system that gave origin to the word which we now accept as signifying maritime sanitation, rather than forty days' detention of suspected or exposed persons.

The regulations of the health officer regarding the inspection and handling of suspected or infected persons, either at the port of embarkation, at quarantine, or on shipboard are well considered. The recommendations that are made regarding needed improvements at quarantine should, when carried out, make this station as effective as it is possible for such an establishment to be.

THE TREATMENT OF HEART DISEASE BY THE SCHOTT METHOD.

DR. R. H. BABCOCK publishes in the *Journal of the American Medical Association* for November 11th an interesting paper on the Schott method of treating chronic diseases of the heart by baths and gymnastics, and his paper is the more deserving of serious consideration because he has personally tried this treatment and has experienced great benefit therefrom.

The method has been employed at Bad Nauheim during the past twenty years in the treatment of all forms of chronic heart disease, except aneurysm of the heart or large vessels and advanced general arteriosclerosis. Valvular disease forms no contraindication to its employment, for most striking restoration of compensation has been obtained in cases of the utmost gravity that had resisted all other forms of treatment.

The method consists in the administration of warm baths, either saline or saline and containing a large percentage of carbonic acid, at a temperature varying from 86° to 92° F. The duration of the bath is from five to twenty-five minutes, being short at first and gradually lengthened. The simple saline baths at the higher temperature are first employed, and they are subsequently gradually and cautiously strengthened by the addition of a strong solution of the salts, and the temperature is gradually reduced. The baths are taken once every second day or daily for three days in succession with one day's interval following. After the bath the patient remains undressed and lies down, warmly covered, for at least an hour. The treatment extends over a period of from five to seven weeks.

Another factor in the method is the employment of extremely simple but systematic exercises of the trunk and limbs. A fundamental principle of the gymnastics is that the patient's movements are restricted by another person. The exercises consist of flexion, extension, and rotation movements. A movement should never be immediately repeated, but followed by a short period of repose. It should not be made so rapidly or against such a degree of resistance as to cause acceleration of the pulse or respiration. All movements must be carried out slowly and steadily, without jerkiness. In some cases the patient resists his own movements by calling into play antagonistic muscles.

During the baths there is a slowing of the pulse with increased volume and strength, and irregularity, if any exists, is lessened or disappears. The cardiac contractions are increased in vigor and the cavities better emptied, thus permitting of a diminution in the size of a dilated heart. This marked and beneficial effect on the action of the heart does not disappear

at once, but persists for a considerable time subsequent to the baths. If properly administered, the baths occasion a gradual and perceptible amelioration of the symptoms. During the gymnastics the rate of the pulse falls and the volume and strength are increased.

While Oertel's method is limited to cases of heart disease in which compensation has not been lost, Schott's method is applicable to a greater variety of cases, and, as the treatment can be carried out in this country by artificially prepared baths and the gymnastics, it seems that by careful selection patients subjected to this treatment may be greatly benefited.

MINOR PARAGRAPHS.

A DECLINE IN PATENT MEDICINES IN GREAT BRITAIN.

THE *Chemist and Druggist* gives an instructive comparative study of the popularity of patent medicines, as indicated by the average annual sales of revenue-tax stamps. The law in Great Britain requires a stamp to be affixed to all proprietary remedies, and the sale of these stamps shows the popular demand from year to year. During a period of twenty-seven years, ending in 1887, the average annual increase was \$25,000; during the period of five years ending in 1892 the average annual rise was \$72,000; but in 1892-'93 there was a decided decrease, amounting to nearly \$100,000 in the twelve months ending in March of this year. This falling off represents a failure on the part of the drug-consuming public to buy three millions of packages—bottles or boxes—of medicines having a selling value of \$750,000. The Pharmaceutical Society has in part been responsible for this remarkable change. The society has lately been insisting on the enforcement of a regulation that requires all patent compounds that contain poisonous drugs to bear a poison label. This has had the effect of embarrassing the sales of that particular line of nostrums and of scaring off many consumers. The scare is beneficial, not only because it affects primarily the more deadly of the patented compounds, but also because it engenders distrust, inquiry, and delay in regard to other purchases of substances that are not required to wear the poison label. It tends to throw a veil of suspicion over every department of nostrum-vending, and is for that reason a sort of indirect educator of a suffering public.

CARBOLIC ACID.

DR. L. DERVILLE, of Lille (*Province médicale*), reports success with carbolic acid in the treatment of vegetations on the genital organs. His experience leads him to urge the more general employment of this drug as a cauterant. There seems to be a diversity of opinion in regard to the indiscriminate use of this drug as a domestic remedy. At a recent meeting of the *Société de médecine et de chirurgie pratiques*, at Paris, the consensus of opinion was decidedly against the use of carbolic acid as a household panacea, and the feeling was that, even in the hands of medical men, it was none too safe a remedy. M. Bardet reported the case of a child, three years old, who had been bitten on the finger by a wasp. A compress saturated with the acid had been applied, gangrene had followed, and a finger had had to be amputated. M. Olivier had observed the case of a young man who had discovered a suspicious sore upon the glans penis, and had applied carbolic acid to the spot. A few days afterward gangrene of the prepuce had come on, producing a veritable circumcision.

THE LATE SIR ANDREW CLARK, OF LONDON.

THIS eminent consulting physician, president of the Royal College of Physicians, died at his residence, as we stated last week, on November 6th, from the effects of an apoplectic attack. The attack occurred on the morning of the 19th of October, while he was seeing some patients in his study. He was found to have right hemiplegia with aphasia, and was going on fairly well, although the paralysis still continued, when he got a relapse on November 3d, and succumbed three days afterward. He was never a strong man, but by careful attention to diet and other matters he attained the age of sixty-seven years. An anecdote is told as bearing on this matter. When very young he applied for his first hospital appointment, and would have been unsuccessful had not one of the governors made a strong appeal in his favor, saying, "Give it to him, as it will please the poor chap, and he can not live long." He was for many years the medical attendant of Mr. Gladstone, who must feel his loss acutely. Sir Andrew Clark's reputation was world-wide, and he attained to every distinction that could be conferred.

DEATH IN RECREATION.

THREE deaths from injuries during foot-ball play have recently been reported in this country, one in New Jersey, one in Indiana, and one in Wisconsin. One lad had his neck broken, and another suffered from fracture of the skull. A recent number of the *Lancet* reports a death by hockey, arising from the use of a hard cricket ball. The player who lost his life was struck by the ball in the cardiac region, the ball having been struck with great force and at short range. The *Lancet* states that this is the first hockey fatality that has been recorded since the adoption of the hard ball, and it advises that the rules of the game be so framed that the softer ball shall be alone admissible. The rules of foot-ball in England have been amended with advantage under the insistence of the *Lancet* and some other journals, but these advocates for humane play are not yet satisfied. They continue to call for more humane rulings.

THE NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

THE annual statement of this excellently managed society has just been issued, and from it we learn that there are now a hundred and forty-three members. During the year the society has extended aid to eleven widows and three children of deceased members. The admirable financial management has made a net increase of almost seven thousand dollars in the capital of the society, the total assets being a few hundred dollars short of a hundred and ninety thousand dollars. What a tribute these figures are to the good judgment and energy of the founders of an organization that is about to enter upon its fifty-second year! It is a matter of surprise that a society that offers so much to its members does not include in its membership the name of every reputable physician in New York. From a financial standpoint no better investment could be made than by joining it, and from a philanthropic standpoint the members of the medical profession should do all that lies in their power to relieve the destitute widows and orphans of deceased members of their guild.

AN UNSUCCESSFUL ATTEMPT AT DISCIPLINE.

INSINUATIONS and covert accusations against prominent members of the medical profession are too common. It is true

that they get little if any attention from men of weight in the profession, but sometimes they do more than tickle the ill-nature of the small fry—they occasionally meet with such credence as to lead to proceedings in a medical society. An account of a case in point we reprint in another column from a Washington newspaper. The gentleman against whom the inquiry was directed in this instance, Dr. William A. Hammond, of Washington, seems to have undergone investigation unscathed, as was to have been expected, and it is to be hoped that, for a time at least, persons who delight in circulating damaging rumors will be somewhat less ready with their tongues.

POST-VACCINAL ERUPTIONS.

At the present time, when such great numbers of persons are being vaccinated, it is well to know the cause of certain symptoms coming on after vaccination. When severe inflammatory symptoms with pustular eruptions on the arm and over the body have appeared after vaccination, an explanation of the condition has been found in the fact that pyogenic microbes have been discovered in many specimens of vaccine virus. M. H. Comte, in the *Revue générale de clinique et de thérapeutique* for October 18th, has made an extended study of these conditions and of their probable cause, and has been able to substantiate this statement.

CÆCAL HERNIA.

M. FEUERER, in the same journal, describes two cases of infantile eclampsia caused by cæcal hernia. In one, a fatal case, the child, six months of age, had died in convulsions. It was found at the autopsy that the appendix had become strangulated in the inguinal canal. In the other case, in which the symptoms of hernia of the cæcum had been present at the same time with the eclampsia, a prompt operation for radical cure had saved the child.

BACTERIA IN SUGAR OF MILK.

DR. A. NAUMANN, of Berlin, has found that the milk sugar of the shops is frequently contaminated with micro-organisms having their source in the milk used in the production of the sugar. He has found that sterilized milk is coagulated after the addition of sugar of this nature.

A HOME FOR EPILEPTICS IN BROOKLYN.

AN effort is on foot in Brooklyn to establish a non-sectarian home for epileptic patients. A suitable lot has already been secured, and it is desired to raise a building fund of not less than \$10,000.

ITEMS, ETC.

A New Maternity Hospital at Nos. 523 to 537 East Eighty-sixth Street was dedicated by His Grace Archbishop Corrigan on last Sunday. The new east wing that has just been erected is seventy-five feet wide, a hundred and thirty-eight feet long, and five stories high. It contains a hundred and fifty beds, and is entirely under the medical supervision of Dr. T. J. McGillicuddy, assisted by a corps of nurses specially trained for obstetrical work. It is intended to build the west wing within a few years.

Medical Director Kidder, of the Navy.—Dr. Benjamin H. Kidder, recently a medical inspector in the navy, has received his promotion to the grade of medical director.

The City (Charity) Hospital.—Dr. William K. Otis has been appointed to fill the vacancy on the visiting staff caused by Dr. Robert W. Taylor's resignation.

Change of Address.—Dr. M. Gross, to No. 1042 Lexington Avenue.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 5 to November 11, 1893:*

STEPHENSON, WILLIAM, Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for four months.

TAYLOR, BLAIR D., Major and Surgeon, is changed from the station, old post of Fort Bliss, Texas, to the new post of that name, and he will report in person to the commanding officer of the latter-named post for duty.

By direction of the Secretary of War, the appointments of QUINTON, WILLIAM W.; BRATTON, THOMAS S.; HOWARD, DEANE C.; PORTER, ALEXANDER S., and WILSON, WILLIAM H., to be assistant surgeons, with the rank of first lieutenants, to rank from October 26, 1893, are announced. They will report in person without delay to the president of the Army Medical School in this city for the course of instruction prescribed in General Orders No. 78, A. G. O., September 28, 1893.

Promotions.

COMEGYS, EDWARD T., Captain and Assistant Surgeon, to be surgeon with the rank of major, October 26, 1893.

GLENNAM, JAMES D., First Lieutenant and Assistant Surgeon, to be assistant surgeon with the rank of captain, October 29, 1893.

BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon, to be assistant surgeon with the rank of captain, October 29, 1893.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 11, 1893:*

MARTIN, WILLIAM, Surgeon. Ordered before the Retiring Board.

BLACKWOOD, N. J., Passed Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the Norfolk Hospital.

CRAIG, T. C., Passed Assistant Surgeon. Ordered to the Navy Yard, New York.

STONE, E. P., Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, and ordered to the Marine Rendezvous, Boston, Mass.

WILSON, G. B., Passed Assistant Surgeon. Detached from the Marine Rendezvous, Boston, and ordered to the Naval Hospital, Chelsea, Mass.

KIDDER, B. H., Medical Inspector. Promoted to the grade of medical director.

GARDNER, JAMES E., Passed Assistant Surgeon. Promoted to the grade of surgeon.

CRAWFORD, MILLARD H., Passed Assistant Surgeon. Promoted to the grade of surgeon.

Society Meetings for the Coming Week:

MONDAY, November 20th: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, November 21st: New York Academy of Medicine (Section in General Medicine); New York Obstetrical So-

cety (private); Medical Society of the County of Kings, N. Y.; Ogdensburg, N. Y., Medical Association; Medical Society of the County of Westchester, N. Y.; Baltimore Academy of Medicine.

WEDNESDAY, November 22d: New York Pathological Society; New York Surgical Society; Metropolitan Medical Society, New York (private); American Microscopical Society of the City of New York; Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.

THURSDAY, November 23d: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, November 24th: Yorkville Medical Association, New York (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, November 25th: New York Medical and Surgical Society (private).

Proceedings of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of October 25, 1893.

Report of a Year's Work in Minor Gynecological Surgery in the Kensington Hospital for Women.—Dr. CHARLES P. NOBLE read a paper with this title. He had been led to make this report of his last year's work in minor gynecological surgery by the fact that very little at this time was written about this subject. Whether this was because gynecologists looked upon these matters as having been settled, or because their attention was more largely occupied with the problems of abdominal surgery, was an open question. He believed it was the latter, as even cursory reading of such articles as had appeared during the past few years showed a great diversity of opinion about the subject under discussion. In his judgment, there was no class of work of more importance in the relief of suffering than minor gynecological surgery, and this estimate of its value, under proper conditions, became more emphatic with increasing experience. He hoped to point out in the comments upon the work reported wherein some had failed to achieve the good results which they had expected, and where others had done positive harm by their work in this field.

There had been one hundred and forty-five operations in minor surgical gynecology performed in the hospital during the past year without a death. The operations had been divided as follows:

Perineorrhaphy and trachelorrhaphy.....	24
Dilatation and curetting.....	28
Perineorrhaphy.....	20
Trachelorrhaphy.....	9
Colporrhaphy.....	10
General operations.....	37

It would be seen that in twenty-four cases the cervix and perineum had both been sutured, that in twenty cases the cervix alone had been sutured. These facts were of practical interest as indicating that, as a rule, when the cervix was torn the perineum was also torn, while the reverse did not hold good. When the disproportion between the head and the cervix was sufficient to cause laceration of the cervix, as a rule, the same accident happened to the perineum; at the same

time, the cervix might escape and the perinæum be torn, either because of its faulty structure or because of mismanagement of the second stage of labor.

Trachelorrhaphy.—This operation had been performed twenty-six times; twice alone, and twenty-four times together with the restoration of the perinæum. The author's estimate of the value of this operation remained unchanged. When the cervix was torn, the womb was enlarged, the lips of the cervix were everted and eroded, with catarrh of the cervix and of the corpus, and especially when, in addition, menorrhagia and metrorrhagia were present, there was nothing which would bring about the cure of the patient so rapidly, thoroughly, and satisfactorily as Emmet's operation on the cervix. It was true that by prolonged treatment of a general character, and with local treatment to reduce pelvic congestion, very many women with laceration of the cervix could be made reasonably well; but this was accomplished only after tedious effort, and then the condition of the woman was not so good as it would have been had she submitted to operation. When properly done, and with proper indications, the operation was practically without danger, and yielded very definite and positive good results. Much harm, however, had been done by operating upon the cervix in improper cases; and also, many patients had not been cured because the work had been poorly done. It was hardly rational to expect to cure a woman having diseased uterine appendages by sewing up her cervix; yet this had been done very many times, with the result that the tubal disease had been made worse, a peritonitis having immediately ensued as a direct consequence of the operation, or resulted later through aggravation of the tubal disease. It should be laid down as a fixed law that the cervix should not be sutured unless the uterine appendages were healthy.

It was his practice invariably to dilate and curette the uterus before performing a trachelorrhaphy, and catarrh of the cervix and corpus, existing as a complication, were thus removed. The cavity of the uterus was thoroughly washed out after the curetting, and thus the field of operation was made more thoroughly aseptic, and the possibility of infection by septic discharges from the endometrium greatly lessened. The principles of asepsis were as rigidly maintained as when doing abdominal surgery. The vagina was thoroughly scrubbed with soap and water after the patient was anesthetized; it was then thoroughly washed with clean water, and afterward with bichloride-of-mercury solution. This preparation of the field of operation preceded all operations upon the utero-vaginal canal.

In performing trachelorrhaphy the writer had the patient in the lithotomy posture, and removed the diseased and cicatricial tissue usually with the knife, at times with scissors, being careful to provide for an ample cervical canal; the rent was sutured with full-curved needles, using catgut as a suturing material. Of the very many cervix operations that he had performed, he had yet to see a case in which primary union had not been obtained. All suturing materials—silver wire, silkworm-gut, silk, and catgut—had been employed, and the results obtained had been the same; hence, as it was usually necessary to operate on the perinæum at the same sitting, he employed catgut, because this suture material was absorbable, and the stitches did not have to be taken out.

In cases in which the cervix was thoroughly diseased, either by cicatricial tissue or by cystic degeneration, he believed it was better to perform Schröder's operation rather than trachelorrhaphy; in the few cases in which he had performed Schröder's operation from this indication the results had been very satisfactory.

Dilatation and Curetting.—During the past year there had been twenty-eight such operations. This operation had always

been done for well-marked endometritis, especially if this was accompanied by marked uterine hemorrhage, also for certain cases of dysmenorrhœa. When the pain of menstruation came on with or after the onset of the flow, and was distinctly intermittent and cramp-like in character, especially if clots were passed from time to time—the passage of the clot being followed by relief of the pain—dilatation and curetting of the uterus had given excellent results. The trouble lay in the selection of the cases. If every woman who suffered pain during menstruation should have her cervix dilated, undoubtedly more harm than good would be done, because in most cases the difficulty was not a narrow cervical canal. It was only in those cases where narrowness of the cervical canal was the cause of the trouble that dilatation would be of service. At times, as a result of the narrow cervical canal and the consequent interference with the discharge both of the menstrual and of the intermenstrual secretions, endometritis had resulted, for the relief of which curetting as well as dilatation was necessary. If the cases were well studied and the dilator and curette only employed in such cases of dysmenorrhœa as had been referred to, the results obtained would be very satisfactory. The cause of the narrow cervical canal of most importance was a lack of development of the uterus, especially of the *portio vaginalis*.

Much had been written within the last few years of the direful effects of the use of the dilator and curette. The attack upon this operation had been led by Dr. Price, and all manner of evil consequences had been ascribed to it. Dr. Price had gone so far as to say that the use of these instruments in the hands of others was the reason why he was kept busy doing abdominal surgery. The author could not believe that this was so, because it was so directly at variance with his own experience. He had used the dilator and curette literally hundreds of times, and had they been the instruments of evil described by Dr. Price he should have had the evidence of it in his own work; on the contrary, only good had resulted, the exceptions being so rare as to be distinctly remembered, and the reason for such ill results had been distinctly apparent. They had been cases (some three in number) in which, although it had been recognized that the uterine appendages were diseased, it seemed best to use the curette to arrest uterine hemorrhage. In these patients the tubal disease had been made temporarily worse, yet none of them had died, and their prospects of cure by means of the radical removal of the tubal disease had not been lessened. It was easy to understand that much harm could be done with the dilator and curette if they were used in the presence of tubo-ovarian disease, especially if the appendages contained pus. It would have been very easy, under these conditions, to cause a leakage of pus into the peritoneal cavity and peritonitis. Both on this account and because it was irrational to expect to cure such a patient by the use of the dilator and curette, in his judgment, under those conditions, these instruments should not be employed, or only under exceptional circumstances. He believed that the ill consequences attributed to dilatation and curetting had been due to this error in the selection of cases, and that in the many cases referred to by Dr. Price, in which the author believed that serious disease of the appendages had been caused by the use of the dilator and curette, in reality the uterine appendages had been diseased before dilatation and curetting had been done, and that this disease had simply pursued the usual course, or perhaps had been aggravated by the treatment adopted. Under proper aseptic methods, dilatation and curetting of the uterus, when the tubes and ovaries were healthy, was a harmless procedure on the one hand, and upon the other hand was one capable of doing great good in the special class of cases of dysmenorrhœa referred to, and whenever endometritis existed.

The author's opinion concerning the safety with which the uterus could be dilated and curetted under the conditions laid down had been strengthened by the work of certain New York surgeons, especially Dr. Polk, who had employed dilatation and curetting of the uterus in a large series of cases in which the appendages had been diseased, and this, he maintained, not only without harm, but with benefit, especially in cases of catarrhal salpingitis. While Dr. Polk's practice and experience had not induced the writer to extend the indications for this operation in his work, yet they bore heavily against the argument that dilatation and curetting were so potent for evil.

Perineorrhaphy.—There had been forty-four cases of perineorrhaphy during the year. Emmet's method had been followed, and the results obtained had been most gratifying. Primary union had been obtained in forty-two patients; in two cases infection and suppuration had prevented union. Emmet's operation upon the perineum was a most admirable addition to surgery, and by its results had been obtained, where the injury was extensive, involving the levator ani muscles, which could not be obtained by the methods usually employed. He believed that this operation was the chief work that Dr. Emmet had given to the profession, and of itself would be enough to give him lasting fame. He had been prepared to accept Emmet's operation by his training in an obstetrical hospital, where careful study of many lacerations of the perineum during labor demonstrated that these lacerations never were median, except at the posterior commissure of the vulva. At the plane of the hymen, which corresponded to the deep perineal fascia, the laceration always became lateral: it extended up one or both sulci of the vagina, and, aside from the skin, mucous membrane, and connective tissue, involved a laceration of the perineal fasciæ and the transversus perinei and levator ani muscles. A rational operation should have had for its object the bringing together of these sundered structures. The denudation must have involved the torn commissure of the vulva and the torn sulci of the vagina. The credit of recognizing this fact was due to Emmet.

The originators of the old median operations, the best of which was Hegar's, had not recognized these facts, and indeed they had based their operations upon the old erroneous teaching concerning the perineal body. The aim of all such operations had been to build a buttress of tissue between the vagina and the rectum, with the idea that it, because of its wedge shape, would act as a support to the pelvic organs. It had not been recognized that the support of the pelvic organs depended upon the integrity of the levator ani muscle and the pelvic fasciæ, and that the object of the operation, when these structures were torn, was to restore them as nearly as possible to their original condition.

In performing the operation the author had usually denuded higher up the sulci than Dr. Emmet did, and had taken care to secure a small introitus by carefully denuding and suturing the torn posterior commissure of the vulva. Catgut sutures had been employed high up in the sulci, and silk sutures through the torn ends of the levator muscle and for the remaining sutures. The results obtained from this operation were more certain and satisfactory than from any other in gynecology. When a woman had suffered from severe injury of the levator ani muscle and pelvic fasciæ, she had all the symptoms of a hernia; she felt as though the pelvic contents were dropping out. To restore the pelvic floor in such a case to its normal condition was to make the woman a new creature.

Procidentia.—There had been ten operations for procidentia, either partial or complete. The method employed in operating for procidentia, excepting in one case, had been to perform first a high amputation of the cervix. The vagina was

cut loose from the cervix, the bladder being pushed off in front and the peritonæum behind. The lateral attachments of the cervix were ligated and cut away, and then about an inch of the cervix was amputated; the cut vagina was then stitched to the cervix and the mucous membrane of the vagina to the cervical endometrium, in this way covering the stump of the cervix with mucous membrane. Next anterior colporrhaphy was performed. Stoltz's method was used when there was much cystocele, otherwise the ordinary oval denudation. And, finally, Emmet's perineorrhaphy was done, the denudation being made as extensive as possible, the object being not to restore the parts strictly to their normal position, but, in addition to this, to make the vagina and the introitus as small as possible.

The author had used this method of operating for four years, and his experience was that by it fully ninety-five per cent. of cases of procidentia could be permanently cured. He knew of only one case in which it had been a complete failure.

Procidentia of the uterus, almost without exception, was due to laceration of the pelvic floor, involving the pelvic fasciæ and the levator ani. As a consequence of this injury the pelvic viscera were not properly supported, and procetocele, cystocele, and prolapse of the uterus ensued. This result was brought about more rapidly in women obliged to do laborious work, and was favored also if for any reason the womb was enlarged and retroverted. The exceptions to this rule were extremely rare; he had seen but one himself. This had been a case of complete procidentia in a nulliparous woman. She had been obliged to do laborious work involving much lifting; her womb doubtless had become retroverted, and as she naturally had lax tissues, the intra-abdominal pressure had forced down the uterus, distended the perineum, and turned the vagina inside out. As illustrating the nature of the case, she had been completely cured by the use of tampons and the pessary. It was important to insist upon the curability of procidentia, because the reverse of this teaching had been advanced of late, and it had been urged as a reason for performing hysterectomy for procidentia. In his judgment, this procedure was illogical unless the uterus contained a tumor or was of great size. It might be advisable also in those rare cases of long-standing procidentia and procetocele, in which the tissues of the pelvic floor had become atrophied from long-continued overdistention, which prevented the restoration of the pelvic floor.

The philosophy of the method of operating for procidentia which had been advocated was clear. By amputating the cervix the size and weight of the uterus were decreased; and a further gain was made by the removal of the cervix, as this, when present, favored the prolapse of the uterus by acting as a guide down the vaginal canal, being deflected forward as the uterus descended by the posterior wall of the vagina. By means of the anterior colporrhaphy the slack of the bladder was taken up and the anterior vaginal wall became a straight line from the pubic arch to the cervix, as it should be. And, finally, the operation upon the perineum restored the integrity of the pelvic floor and insured a permanent cure by affording an adequate support to the pelvic viscera.

General Operations.—The thirty-seven general operations had consisted of the removal of polypi, the excision of papillomatous about the genitalia, scraping operations for cancer in cases in which the disease was too advanced for a radical operation, the closure of two vesico-vaginal fistulae, excision of the mammary gland, etc. As the author had no suggestions to offer in the performance of these operations that differed from the accepted teachings, it was unnecessary to discuss this subject.

General Considerations.—Success in minor surgical gynecology, and especially in plastic work, depended upon a thor-

ough gynecological training, and especially upon a knowledge of the anatomical side of the pathological conditions involved, upon the faithful employment of aseptic methods, and especially upon careful work in suturing. Thorough preparation of the field of operation by careful scrubbing with soap and water and plentiful douching with plain boiled water, followed by bichloride-of-mercury solution, were just as important in this class of work as in any other. With an aseptic field, with aseptic sutures and instruments, and with aseptic hands, primary union should be almost invariably obtained. In his entire experience in operating upon the utero-vaginal canal he could recall only three cases in which primary union had not been obtained, and in only one or two more had infection along the sutures resulted in the formation of pus; and in these cases primary union had not been prevented.

The suturing material employed in this class of work was somewhat a matter of indifference, as a good operator could obtain perfect results with any of the recognized suture materials, provided it was aseptic. The author had long given up silver wire because it was troublesome to use and possessed no real advantage for this work. Silk-worm-gut was a most excellent material, but was stiff, and therefore the stitches were more painful to remove than silk stitches; for this reason, unless there was good cause to fear infection, he did not employ it. In complete lacerations of the perineum into the bowel it should be used in preference to silk. Properly prepared catgut had given him complete satisfaction. This he thought was because it had been used only when no tension was to be feared. In the cervix it answered perfectly; also for the upper sutures in the perineum. Wherever tension was expected silk had been employed, and answered every expectation. He should have hesitated to use catgut for the lower important sutures in performing perineorrhaphy, because straining at stool or coughing on the third or fourth day, when the catgut sutures had become weakened, might have caused the wound to burst open. There was little difficulty in removing four or five silk sutures from each sulcus of the vagina; and the advantage that the silk would sustain the straining at stool or coughing more than compensated for the trifling discomfort of removing these sutures.

In placing sutures, the operator should always bear in mind what he wished to accomplish with the suture; if he desired to make surfaces unite the one to the other, the suture must be placed so that when tied it formed a circle, or nearly a circle. In this way the surfaces were brought together smoothly, and were held together. Superficial sutures placed parallel to the surfaces which it was desired to unite acted as puckering strings, threw these surfaces into folds, and defeated the object aimed at. This apparently simple matter made all the difference between success and failure in plastic work.

The Treatment of Acute Pneumonia with Ice and Supporting Measures.—Dr. THOMAS J. MAYS read a paper with this title. Acute pneumonia, he said, was a disease which we all well recognized. Its symptoms and physical signs, its course and duration, were constant and characteristic; yet, strange to say, its treatment was as variable and vacillating as its death-roll was long and appalling. In the city of Philadelphia alone fifteen hundred lives were annually sacrificed to this disease. Was this frightful mortality inevitable, or was there a way to escape it? He believed that it could be materially lessened, but before this could be done we must realize the shortcomings and the mischievous tendencies of professional thought on this subject at the present day. He believed that the want of uniformity in the therapeutics of this disease was partly traceable to the prevailing but mistaken theory that pneumonia, like measles and small-pox, was a self-limited disease, and therefore

beyond the touch of successful active medication. Then, again, the general skepticism of this age had invaded the field of therapeutics and had cast a gloom of doubt on the remedial effects of the long-honored articles of our materia medica. Both of these tendencies in connection with the fact, which had been shown over and over again, that the practical results of the let-alone treatment of pneumonia were superior to those which were obtained when the disease received the active routine treatment of days gone by, had brought the therapeutic art into undeserved discredit, and had sown broadcast a belief that the less active the treatment to which pneumonia was subjected, the better it was for the patient. In accordance with this view, the disease pursued its natural course in spite of any treatment, and all that could be done was to stand by and watch and treat any incidental danger which might develop.

What ground was there, then, for believing that the pneumonic process was self-limited, and that the therapeutic art was powerless in making a local impression on it? So far as the author could see, there was no more reason for regarding pneumonia as self-limited than there was for considering any other ordinary acute disease in the same light. All diseases of this kind were limited in duration, but there was no inherent limitation, in the same sense as there was in small-pox or measles. Let us say pneumonia suddenly attacked a single lobe of a lung, and in the course of three or four days it suddenly ended in crisis, and every vestige of the disease disappeared. Its sudden onset and termination in many instances led us to infer that pneumonia was due to the absorption and explosion of a specific poison, which exhausted its energy in a few days, and to see an analogy between its behavior and that of small-pox. On the other hand, let us suppose another case of pneumonia involving the same lobe of the lung. In about three days the temperature suddenly dropped to within a degree of the normal line, and a favorable termination was anxiously looked for, but, instead of this, the temperature rose higher, and on physical examination it was found that the whole of the adjoining lobe was implicated in the process. A similar succession of events might take place in case another lobe or part of a lobe became involved. These phenomena were familiar to every practitioner, and yet could any one say that this was definite proof of the self-limitation of pneumonia? Had any one ever heard of small-pox or measles attacking the body by piecemeal, first invading one area, then another, and so on? Was it not more probable that the duration of the pneumonic process was chiefly governed by the length of time which it naturally took for the fibrinous exudation to undergo fatty degeneration? and that when the fibrinous deposit occurred successively in different lung areas the disease would be more protracted on this account than if it confined itself to the area which became primarily involved?

Moreover, it was the author's firm conviction that the prevailing impression that the pneumonic process could not be controlled or restrained by means of active medication rested on an equally insecure foundation. He was not rash enough, however, to assume that any form of treatment could be devised which would always insure against death from pneumonia, but from recent experience he believed that a mortality of twenty per cent., which was the usual death rate, was too high, and that this might be materially reduced. He also firmly believed that this reduction in the mortality could not be brought about exclusively through internal medication, feeding, or stimulation, valuable as these measures were. The profession fully realized the vital importance of sustaining the strength of the patient throughout this disease, and practically this part of the treatment was carried out with very desirable results. Far above the efficacy of all these measures, however, stood

ice, or ice-cold water—the local application of which had the undoubted power of subduing and of circumventing the inflammatory process in the lung.

He based this favorable opinion on the results which were brought out in his collective report on Ice in the Treatment of Acute Pneumonia, which was published in the *Medical News* for June 24, 1893. This paper consisted of the condensed histories of fifty cases which were treated locally with ice or cold applications, and which were reported to him by professional friends, or were collected from the literature on the subject, or came under his personal observation. Out of the entire number of patients, two had died, making a death-rate of four per cent. Additionally he referred to one hundred and six other cases of pneumonia treated in the same way by Dr. Fieandt, a physician of Finland, who had a mortality only of 2.82 per cent.—giving a death-rate among all of these cases of 3.2 per cent. Moreover, since the appearance of his paper he had succeeded in securing a number of other reports of cases thus treated, which continued to maintain the favorable impression made by the ice treatment in the first report, and which he hoped to include in a future contribution on this interesting problem.

Aside from the fact that both of the patients who died among those reported in his list had suffered from probably incurable diseases when they were smitten with pneumonia, and were, perhaps, on this account not the most impartial test for any new remedy, it was quite evident that the total showing was still better than appeared on the surface. Great weight must, he thought, be laid on the fact that these cases emanated from fourteen independent observers, half of which number report only one case each. This excluded largely the existence of a personal factor—an attribute and a power which grew out of accumulated knowledge and experience and gave its possessor a certain advantage over those less equipped in this direction, and went far to demonstrate that the curative effects of ice applications did not depend on any very special artistic skill of the medical attendant.

The author often asked whether ice was as efficacious in catarrhal as it was in croupous pneumonia. On theoretical grounds one would be led to believe that it was of greater service in the latter than in the former variety, because the whole inflammatory process was more ephemeral and entailed less organic change on the lungs in that form. While his first cases in which the ice was used had been exclusively those of the croupous variety, his later experience had taught him that this measure had a similar beneficial effect in catarrhal pneumonia, provided it was pursuing an acute course. This was fully demonstrated by a number of the cases contained in his report, notably by some of the cases which were treated by Dr. Lees, and also by the one reported by Dr. Franklin. Indeed, he believed it was impossible sometimes to discriminate between croupous and catarrhal pneumonia during life when the latter pursued an acute course, and especially when it took place in infants or small children.

In what special manner should the ice be employed? For want of a better method, the front, side, and back of the affected area were surrounded with rubber bags filled with ice and wrapped in towels. The number of bags which were needed depended on the size of the area which was involved. If this was small, only one or two bags were necessary, but in cases where an extensive area was affected he had applied as many as six and seven, which sufficed to cover the whole chest. They were allowed to remain until the temperature became nearly normal. Very often it was found that the application of the ice to the affected spot was immediately followed by a marked lowering of the temperature and improvement in the physical signs in the part. In a very short time, and perhaps

in the midst of this amelioration, the temperature rose again, and the patient felt less comfortable than before. Further examination showed that the disease had invaded a new and probably an adjoining territory. Removal of the ice bags to the fresh spot, or the application of new ones, would again be followed by improvement. This creeping feature of pneumonia must always be borne in mind and followed up until it ceased.

One difficulty in the use of the ice bags was to keep them constantly applied to the chest in restless patients, and this had led him to look into the feasibility of making a hollow tin jacket, which adapted itself to the chest, and through which a constant current of ice-cold water might be passed. Such an apparatus the author had in contemplation, and when it was perfected he thought it would add much to the effectiveness of the application and would also be a greater convenience to the patient.

The subject of diet demanded the most serious consideration of the practitioner, whose aim should be to administer food of the most nourishing character and in the most concentrated and digestible form. In other words, he should strive to give the stomach as little work to do as possible, and at the same time maintain the nutrition of the patient at the highest point. For this reason two ounces of fresh beef juice pressed out of round steak should be given alternately every hour and a half or two hours, with eight tablespoonfuls of milk, one of whiskey, and one of limewater. Beef powder and nutrient wine of beef peptone might also be given.

So far as internal medication was concerned, he would say that strychnine stood first in this respect and should be given unstintedly. Adults should receive a twenty-fifth or a twentieth of a grain twice a day hypodermically, and a twenty-fifth of a grain by the mouth every four hours, until there was a manifestation of toxic symptoms, such as an increase of the reflexes, especially of the lower extremities. A quarter of a grain of morphia was to be given subcutaneously in the evening to produce sleep. An ice bag to the head would also help to allay cerebral excitability and restore quiet. Evacuation of the bowels should be secured by the administration of small doses of calomel and sodium bicarbonate.

When cyanosis and difficult respiration became very marked, inhalation of oxygen must be employed. The patient might inhale the gas out of an ordinary-sized rubber gas bag through a suitable mouth-piece which was attached to it. The amount of oxygen which must be given in a case was entirely dependent on the severity of the symptoms, but it was a good rule to push it until the lips and finger nails assumed a healthier appearance and the breathing became less oppressed, and to give it as often as it was necessary to suppress these symptoms.

Now, when we compared the results of the ice treatment of pneumonia with those which were obtained from the prevailing treatment, it would show very much in favor of the former mode of treatment. Thus the mortality of one thousand and twelve cases in the Montreal General Hospital was twenty per cent., while in the Charity Hospital of New Orleans it was 20.01 per cent. From 1822 to 1889 the mortality from pneumonia in the Massachusetts General Hospital had been twenty-five per cent. Dr. Hartshorne estimated that the death-rate from this disease in the Pennsylvania Hospital, this city, had been about thirty-one per cent. during the years 1884, 1885, and 1886. A comparison of this mortality rate with that which had been derived from the treatment advocated in the present paper showed that the latter produced results which were at least seventy-five per cent. better than those which were obtained when the cold applications were not employed. He knew that the number of his cases was rather small to draw

such promising deductions, but from his experience since they had been published he was encouraged to believe that this form of treatment would not only maintain its excellent reputation, but grow in increased favor on closer acquaintance.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

Bacteriological and Clinical Observations in Catarrhal Conjunctivitis.—Morax (*Ann. d'oc.*, December, 1892) concludes from his observations that the conjunctival secretion in the epidemic or sporadic catarrhal conjunctivitis so common in Paris always contains a bacillus identical with that described by Koch and Kartulis in the catarrhal conjunctivitis of Egypt, and by Weeks in the catarrhal conjunctivitis of Philadelphia. It is therefore justifiable to class these affections together, and to differentiate between the common catarrh of the conjunctiva which accompanies certain ocular affections and the specific catarrh, contagious conjunctivitis, which contains the above-mentioned bacillus. This morbid product may assume various clinical varieties, which may be recognized by the muco-purulent character of the secretion and by its tendency to contagion, as well as by the bacteriological examination.

The Nature of Trachoma.—Mutermilch (*Ann. d'oc.*, January, 1893) believes that the association of bacteriological investigations with clinical facts, which often belie the contagious character of trachoma, permits us to conclude that we have not yet succeeded in discovering the microbe of trachoma, for the simple reason that the latter does not exist. Owing to the presence of adenoid tissue in the conjunctiva, the regeneration of the epithelium occurs very rapidly, and this easy reproduction accounts for the powers of resistance of the normal conjunctival epithelium to the effects of pernicious agents. The change of character in the epithelium of a trachomatous conjunctiva means that the anatomical equilibrium between the epithelium and its base has been regained, and that the tissue has again become as resisting as it was before the disease began. If the resistance of the normal conjunctival epithelium is due to the vitality of its anatomical elements—that is, to its capacity of reproducing itself very rapidly—if its reason is purely physiological, after the condition of trachoma has ended, this resistance has become passive, due to causes of a purely mechanical nature. From the moment the conjunctival epithelium has assumed the epidermoid type the conjunctiva passes into the second characteristic phase, which has been described as trachoma, or granular ophthalmia. After each inflammatory exacerbation the adenoid tissue becomes richer in connective tissue fibers, the regenerated epithelium becomes more and more epidermoid in character, its superficial cells receive less and less nutrition, they gradually desiccate, and finally become epidermoid, and in this way the trachoma ends.

Influence of the Orbicularis Muscle on the Refraction of the Eye.—Février (*Ann. d'oc.*, February, 1893) differentiates between primary astigmatism which is manifest when the eyelids are widely opened, and secondary astigmatism which is produced when the eyelids are contracted. The direction of the principal meridians of primary astigmatism often remains when the lids are contracted, but this persistence is generally produced in subjects in whom the meridian of shortest curvature occupies a vertical position. In the great majority of

cases the principal meridians, which are more or less oblique, become changed; the meridian of shortest curvature becomes vertical, while the second principal meridian becomes horizontal. In certain rare cases the astigmatism disappears when the orbicularis is contracted. From these considerations Février draws the following conclusions: 1. The palpebral fasciculi of the orbicular muscle exert by their contraction a definite pressure on the whole eyeball. This contraction may finally provoke modifications in the shape of the eye, especially during the period of its development—that is, in childhood. This modification of form will vary according to the form and insertion of the palpebral muscles with reference to the eyeball, very marked in myopes and much less so in hypermetropes. Moreover, the simple tonicity of the muscular fibers may play its part in effecting such change of shape. 2. This pressure produces a secondary effect in shortening the antero-posterior diameter. 3. This pressure, acting especially on the superior and inferior parts of the cornea, produces an exaggeration of curvature of the vertical meridian, which causes an astigmatism in which the principal meridians will be vertical and horizontal, or nearly so, and which, in the majority of cases, will take the place of a pre-existing astigmatism in which the principal meridians were oblique. 4. This pressure explains why astigmatic and myopic patients so often wink the eyelids.

Treatment of Hydatid Cysts of the Orbit.—Terson (*Ann. d'oc.*, March, 1893) advises the following method of treatment: 1. Make a sufficiently large puncture to empty the contents of the cyst, followed by a prolonged injection of aseptic distilled water, in order to facilitate the detachment of the hydatid vesicle and its removal by means of forceps. 2. If these means fail, induce suppuration in the cyst.

The Treatment of Hæmorrhagic Glaucoma.—De Bourgon (*Ann. d'oc.*, March, 1893) draws the following conclusions from his observations: 1. True hæmorrhagic glaucoma presents a grave local prognosis, proved by the great number of enucleations. 2. The different operations proposed for the treatment of the other forms of glaucoma, being useless and painful, with the exception of sclerotomy, ought to be absolutely rejected. 3. The general prognosis being almost as grave as the local, the attention of the physician to the general condition of the patient should be as close and accurate as to the condition of the eye, on account of the possible existence of vascular lesions elsewhere. 4. In the hæmorrhagic period the congestion of the eyeball should be counteracted and the general condition of the patient carefully attended to. In the period of confirmed glaucoma the treatment should always at first be medical—such as eserine, heat, and subcutaneous injections of ergotine. If the acute symptoms do not diminish in intensity, the only permissible operation is sclerotomy, simple or equatorial. Iridectomy should never be performed. If the intra-ocular tension is not appreciably lowered by these means, enucleation should be done at once.

The Diagnostic Value of the Loss of the Pupillary Light-reaction, with a Note on the Oculo-facial Muscular Group.—Turner (*Roy. Lond. Ophth. Hosp. Rep.*, xiii, 3) advises that, in testing cases for light-reaction, the light ought not to be more intense than the eye is usually accustomed to, and hence daylight is better than that reflected from a mirror. All errors associated with accommodation and convergence must be carefully eliminated. In testing the consensual reflex, it is important that the eye under observation should be partially protected, and not exposed to the full influence of the light. Turner considers that the Argyll-Robertson pupil, existing by itself on one or both sides, although not diagnostic, is highly suspicious of the presence of an early progressive, degenerative lesion in the upper portion of the central nervous apparatus, and its

presence should suggest the possibility of other symptoms which may require careful investigation—such as the state of the kneejerks, the condition of the optic nerves, the actual presence of paralysis of some of the external ocular muscles, and, lastly, the presence of defective sensibility in the distribution of the nervus trigeminus. The four reported cases illustrating reflex pupillary immobility on one side are of importance in localizing the situation of the lesion. Laying aside at once an affection of the afferent or efferent limbs of the reflex arc as the cause in these cases, we may conclude that the lesion is situated either in the center for the sphincter iridis in the forepart of the oculo-motor nucleus, or in the fibers which unite the nucleus with the proximal end of the optic tracts. The lesion which causes reflex pupillary immobility on one side, with retention of the consensual reflex, merely blocks the passage of the direct fibers from the optic tract to the oculo-motor nucleus on the same side, while that which produces both direct and consensual immobility of the pupil on one side occupies a position which blocks both the direct and the crossed system of fibers, assuming that there is only one lesion. In endeavoring to localize the seat of the lesion in these cases the size of the pupil, apart from its reaction to light, must be considered. Accepting the view that dilatation of the pupil is due to inhibition of the sphincter iridis, the lesion which causes interference with the passage of impressions along Meyner's fibers paralyzes as well the sphincter inhibitory center. These facts lend support to the view that the center subserving the reflex actions of the pupil consists of two parts—a sphincter-contracting and a sphincter inhibitory center—closely associated in function. The fibers from the former pass to the iris in company with fibers for the ciliary muscle by the third cranial nerve, while those from the latter pass down to and through the cervical portion of the spinal cord, and enter the sympathetic through the lower cervical and upper dorsal nerve roots. The study of Turner's cases suggested to him the following subdivision of the fore part of the oculo-motor nucleus: 1. A sphincter-inhibitory center, closely associated with a sphincter-contracting center, which two subserve the pupillary light-reflex. 2. A center for accommodation. 3. A center for contraction of the pupil with convergence, in close association with the center for the associated action of the internal recti muscles. Turner believes that the frontalis and orbicularis palpebrarum muscles, although peripherally supplied by the facial nerve, are "eye muscles," and form the oculo-facial group.

The Influence of Tobacco on the Sight.—Dowling (*Rec. d'Ophthalm.*, October, 1892) draws the following conclusions from his investigations: 1. The subjects examined were between the ages of thirty and sixty years, with the exception of one young man of nineteen, and were all workers in tobacco manufactures. 2. In almost all the cases examined there was noted a gradual diminution in the visual acuity of both eyes. 3. The majority of the patients saw better in the semi-obscurity of the workshop than in the street. 4. There was color confusion, principally of red and green. 5. The most frequent symptom was contraction of the pupil, and this was most marked in those patients who smoked as well as chewed.

Pseudo-glioma.—Collins (*Roy. Lond. Ophth. Hosp. Rep.*, xiii, 3) defines pseudo-glioma as any condition of the eye liable to be mistaken for true glioma, and applies the term to three classes of cases: 1. Those in which there is a persistence and thickening of the posterior part of the fetal fibro-vascular sheath of the lens, or an atypical development of the anterior part of the vitreous, with or without a persistent hyaloid artery. 2. Cases in which large masses of tubercle occur in the chorioid. 3. Cases in which there has been inflammatory effusion into the vitreous, following a retinitis and cyclitis, and in most cases

accompanied by detachment of the retina. In this latter class of cases the eye symptoms are frequently preceded by some acute febrile condition, in many cases by head symptoms of greater or less severity, pointing to meningitis and rendering it highly probable that in all the cases in which cerebral symptoms are obtained some inflammation of the meninges has occurred. The connection between the intra-ocular inflammation and the meningitis might be embolic or one of direct extension along the optic nerve.

In glioma of the retina the appearance of the opacity behind the lens varies considerably according to the relation of the growth to the retina. When it springs from the outer surface—glioma exophytum—the growth is viewed through the retina, and a mass with smooth surface is seen, having enlarged retinal vessels on it, close behind the lens. If it springs from the inner surface of the retina—glioma endophytum—the ragged surface of the growth itself is seen far back, often with little secondary floating nodules in front of it and no retinal blood-vessels on its surface. The reflex obtained from a persistent and thickened posterior fibro-vascular sheath is usually grayer than that from a glioma, and this gray opacity may be confined to the central portions of the posterior part of the lens, a red reflex being seen through it at its extreme periphery in all directions. When the central hyaloid artery is persistent and patent, some of its branches may be seen coursing through the gray membrane. An inflammatory membrane behind the lens may have new blood-vessels developed in it, but these are smaller than retinal blood-vessels. There is nothing distinctive about the appearance of the opacity seen in a case of tubercle of the chorioid, which simulates glioma. In glioma the lens is often pushed forward and the anterior chamber uniformly shallow. Should it be deepened at its periphery and shallow in the center, the case may be diagnosticated as one in which there has been inflammatory exudation into the vitreous and circumferential space which, in organization and contraction, has drawn back the root of the iris and pushed the lens forward. Glioma here may be absolutely excluded. The anterior chamber in cases of persistence of the posterior fibro-vascular sheath is sometimes very shallow. As regards the iris, posterior synechie are common in cases beginning as retinitis with exudation into the vitreous, and may be met with in connection with tubercle of the chorioid. Their occurrence does not exclude the possibility of a case being one of glioma, for occasionally, though rarely, it is associated with inflammation of the uveal tract. There is as yet no definite proof that in the early stage of glioma of the retina the tension is minus. In glioma of the retina there would not be the same tendency to early pressure on the posterior ciliary arteries that there is in sarcoma of the chorioid, arresting the blood supply to part of the ciliary body and so cutting off the nutrient fluid of the vitreous, causing it to shrink. In cases of pseudo-glioma, with detached retina and exudation into the vitreous, the tension is frequently minus.

The history of fits, unconsciousness, attacks of screaming, ear disease, one of the acute specific fevers, or of symptoms of syphilis preceding the eye affection, would be in favor of the case being one of ophthalmitis. If the opacity was noticed at or soon after birth the case would probably be either glioma or a persistent fibro-vascular sheath. Should the symptoms have been produced by a tubercular mass there might be evidences of lesions of a similar nature in other parts of the body.

Metastatic Inflammations in the Eye, especially the Retinitis Septica of Roth.—Herrheiser (*Kl. Mon. f. Aug.*, December, 1892) agrees with the views of Roth as follows: 1. Retinitis septica occurs much oftener than panophthalmitis, which, without considering other pyæmic processes, is even in puerperal fever a tolerably rare complication. 2. It is distin-

guished by its relatively benign character; the retinal foci are very small, circumscribed though sometimes numerous, and show no tendency to extend. The choroid is rarely affected even by hyperemia and discoloration of its epithelium. 3. Its benign course depends upon the fact that this form of retinitis does not rest upon an embolic process. In none or the hitherto observed cases were any vascular plugs found in the retina. The capillaries in the white patches are either normal of the seat of fatty degeneration, but contain nothing abnormal, and the cardiac valves are not covered by vegetations.

A Peculiar Form of Irregular Corneal Astigmatism complicated by Marked Disturbance of the Relative Accommodation in the Affected Eye.—Axenfeld (*Kl. Mon. f. Aug.*, February, 1893) finds that in all these cases of disturbance of accommodation we must count upon: 1. A very varying and elastic power in the relative accommodation. 2. The former total refraction. 3. The size of the pupil and the activity of its reaction. 4. The size and position of the flattened portion of the cornea and the degree of refractive difference. 5. The diminution of the visual acuity in the region of the flattening and its relation to the individual peripheral visual acuity in different parts of the retina. 6. The unioocular diplopia. All these points must be carefully considered before it is possible to thoroughly comprehend the actual condition of the eye in question.

A Modification of Kuhnt's Operation for the Treatment of Senile Ectropion of the Lower Lid.—Müller (*Kl. Mon. f. Aug.*, April, 1893) prefers the following method of operating: An incision in the intermarginal edge of the lid with a lance knife, separating conjunctiva and tarsus from muscle and skin. The incision begins at the point where the wedge-shaped piece is to be excised and has at first the shape and size of this piece. By lateral sliding of the lance knife the incision is increased by a piece the shape of a rhomboid, which forms a trapezoid with the original section. The length of the intermarginal side of this rhomboid depends on the size of the base of the wedge-shaped piece of tarsus which is to be excised. The wedge-shaped piece is then excised and the intermarginal stitches are then first inserted and afterward the stitches in the tarsus. The advantages of the operation are as follows: 1. The tarsus is firmly maintained in its new position by a broad, superficial adhesion between tarsus and skin. 2. The tension is not put upon the stitches inserted in the tarsus, but upon those passing through both skin and tarsus. 3. Only a slight notch is left in the tarsus. 4. There is no permanent prominence left in the lid.

Excision of Muscular Tissue as an Operation in Squint.—Müller (*Kl. Mon. f. Aug.*, April, 1893) does not approve of the method of shortening the muscle advocated by Noyes and Viennse in the operation for squint in place of tenotomy of one or both internal recti muscles. He thinks it should only be employed in those cases in which tenotomy and advancement are done simultaneously. He would employ it in cases of strabismus convergens, where the abduction of the squinting eye is defective; in all cases of strabismus divergens where the squint deviation is more than four millimetres; and in certain cases of strabismus divergens of three to four millimetres, where one eye has very defective vision. The method he employs is similar to that recommended by Schüssler, and he claims for it the following advantages: 1. The operator can excise a piece of muscle of definite length. 2. The insertion of the muscle can not be displaced upward or downward, and hence the vertical meridian can not be abnormally inclined. 3. There is no marked prominence at the inner or outer limbus.

Toxic Amblyopia from Iodoform.—Smith (*Ophth. Rev.*, April, 1893) reports a case of this kind occurring in a man,

aged thirty-one, who suffered from chronic tubercular pleurisy and periostitis. He had taken during a period of forty-one days one thousand grains of iodoform, and during the last ten days of this period he took thirty-two grains daily. The onset of the amblyopia was associated with headache, giddiness and faintness, diarrhoea, twitching of the hands, emotional depression, and a constant smell and taste of iodoform. The urine became alkaline and contained triple phosphates. There were numbness and tingling in the legs, and the knee-jerks were increased. There was slight haziness of the disc margin in both eyes. Vision was greatly impaired and there was a well-marked positive central scotoma, larger than that usually found associated with tobacco amblyopia. The loss of vision began a day or two before the iodoform was discontinued. Four weeks later there was still a central color scotoma in both eyes with a very small absolute scotoma just below the fixation point. R. E. V. = $\frac{1}{2}$; L. E. V. = $\frac{1}{4}$. Under the use of hypodermic injections of strychnine vision steadily improved, and three months after the onset of the amblyopia it had risen to $\frac{1}{2}$ in each eye, and no scotomata could be found.

Creasote in Tuberculous Iritis.—Quint (*Ctrbl. f. prakt. Aug.*, March, 1893) recommends the use of creasote internally, beginning with 0.3 gramme, in cases of tubercular iritis, and running the dose up to 0.75 gramme daily. It must be persisted in for weeks and even months. The author states that it succeeds where everything else fails, and that he has never seen any bad results from its use.

The Relation of Convergence to Accommodation, and its Practical Bearing.—Percival (*Ophth. Rev.*, November, 1892) draws the following conclusions from his observations: 1. The correction of refractive errors, if of high degree, causes a profound alteration in the relative activities of the nervous centers for convergence and accommodation. Most persons have a remarkable power of adapting themselves to the new conditions caused by such correction, and for them prismatic combinations are unnecessary. 2. For those persons who can not so adapt themselves to the correction, relief will often be given even by weak prisms that diminish the strain. 3. Treatment must be based on the relative and not on the absolute convergence. 4. The "area of comfort" is roughly represented by the middle third of the relative convergence range, and practically the oculist need only concern himself with that which has to do with the vision of objects at and beyond the distance of one third of a metre. 5. The glass-rqd test may be regarded as a roughly qualitative test, but it is not a reliable indication of the strength of prism which is required to give relief in these cases. Percival recommends the following tests: 1. Correct all errors of refraction, and determine the relative range of convergence for 0 accommodation by means of abducting and adducting prisms, the test object being at a distance of at least six metres. 2. Repeat the test with the test object at one third of a metre. This will give the dimensions of the range of either side of the point corresponding to D. 3 of accommodation and 3 metre-angles of convergence. 3. Find the absolute maximum of convergence, in order to determine if the range is much contracted.

The Surgical Treatment of Trachoma.—Stephenson (*Ophth. Rev.*, January, 1892) thinks that "expression" is indicated: 1. In follicular disease in which discrete follicles are scattered over the surface of an otherwise normal conjunctiva. 2. In trachoma of recent origin. 3. In old and obstinate cases of trachoma, where the operation may have to be repeated several times. Excision of the *cul-de-sac* is sometimes very useful in relieving the ptosis of severe trachoma, and Stephenson describes his method of operating in such cases, in which he avoids the use of all sutures in closing the wound.

The Prescribing of Prisms.—Maddox (*Ophth. Rev.*, February, 1893) gives the following maxims in prescribing prisms: 1. Never order them unless the indications for their use are unmistakable. 2. Never order them simply on account of an anomaly in the behavior of the eyes under the various tests unless there is asthenopia, headache, tendency to diplopia, or giddiness. 3. Do not judge by one test, but by the "finger," "rod," and "card" tests, and also by the "relative-convergence" test. 4. Remember that considerable latent deviation in distant vision is more important than in near vision, and that moderate divergence in near vision is physiological. 5. Always more or less under-correct with prisms. Prisms to correct hyperphoria should, of course, be equally divided between the two eyes, and should be edged up before the eye that deviates upward and edge down before the other eye.

Synchysis Scintillans and Spintheropia.—Sgrosso (*Rev. gén. d'ophtal.*, Dec. 31, 1892) draws from his observations the following conclusions: The phenomenon of scintillation is due not only to the presence of cholesteroline, but also to that of tyrosine and the phosphatic salts and to those of margarine. The adipose crystals and the calcareous salts coexist with chronic inflammatory and degenerative changes in the coats and media of the eye.

Keratitis Dendritica and Herpes Corneæ Febrilis.—Emmert (*Contrib. f. prakt. Aug.*, December, 1893) regards keratitis dendritica as a very rare disease, while herpes corneæ febrilis occurs with tolerable frequency. Keratitis dendritica occurs in patients in a perfect state of health and without any febrile symptoms, but these patients are almost certain to be of the scrofulous habit. The disease begins with a subepithelial grayish opacity from which grayish prolongations extend in various directions. Above the subepithelial grayish mole-like tunnels the swollen, grayish epithelium becomes raised, is cast off, and the gray, shallow furrow lies exposed. There is a certain resemblance in the form of the infiltration and the loss of substance to the changes that occur in herpes corneæ febrilis, but here the resemblance ceases.

Blood-cysts of the Orbital and Subconjunctival Cellular Tissue.—Mitralsky (*Contrib. f. prakt. Aug.*, January, 1893) considers that cysts or tumors containing blood are by no means rare occurrences in the orbit. He reports one case in detail, occurring in a woman aged twenty-four years, who had suffered for two days from uncontrollable vomiting. There was a black, oval, elastic blood tumor about as large as a Lima bean beneath the conjunctiva oculi and extending back into the orbit. In two weeks this blood tumor had changed into a semi-transparent ovoid cyst. This was removed and examined microscopically, but not a trace of epithelium or endothelium could be found on the inner wall of the cyst. This same condition he has found in several other cases of similar origin.

The Origin of the Striated Keratitis that occurs after Cataract Extraction.—Hess (*Archiv für Ophthal.*, xxxviii, 4) draws the following conclusions from his observations: 1. The generally prevailing view that the so-called striated keratitis is due to a swelling and infiltration of the corneal substance is not tenable. This loosening of the tissue of the cornea, as well as the occasional hyaline degeneration of this tissue, is only an accidental circumstance. 2. The important anatomical change in this striated corneal opacity is a folding of the deeper portions of the cornea, which is expressed or exhibited in the undulatory course of the corresponding layers. 3. The cause of this folding or reduplication must be sought in the fact that by the opening of the anterior chamber a great difference is at once caused between the tension of the vertical and horizontal meridians of the cornea, which produces the same effect as if the cornea were compressed laterally.

A Tubercular Tumor in the Corpora Quadrigemina, with Bilateral Ophthalmoplegia.—Goldzieher (*Contrib. f. prakt. Aug.*, February, 1893) reports a case of this nature, and draws the following conclusions: 1. A tumor occupying the entire region of the corpora quadrigemina need not necessarily be accompanied by blindness. 2. A typical total external ophthalmoplegia, even accompanied by somnolence, is not necessarily caused by primary changes in the central nuclei of the oculo-motors. 3. Ophthalmoplegia, combined with staggering and disturbances of co-ordination in the lower extremities, points to the location of the lesion in the corpora quadrigemina. 4. Spastic contractions in the extremities, combined with general epileptiform convulsions, are caused solely by lesions in the corpora quadrigemina.

The Margin of the Lens considered Ophthalmoscopically.—Dünmer (*Arch. für Ophthal.*, xxxviii, 4) draws the following conclusions from his observations: 1. The edge of the lens appears dark by transmitted light; not because the light reflected from the fundus upon the anterior surface of the lens is totally reflected near the margin of the lens, but because this light is deflected by the equatorial portion of the lens in such a manner that it can not enter the hole in the ophthalmoscopic mirror, and is therefore not perceived by the observer. 2. By oblique illumination the margin of the lens appears as a bright white or yellowish glistening line by total reflection of the light on the posterior surface of the lens, when the lens is dislocated into the anterior chamber. The light must be enabled to pass through the equator of the lens itself and through the neighboring portions of the anterior surface of the lens, in order to be totally reflected on the other side of the equator of the lens. 3. If the lens is so dislocated that a portion of the equator of the lens is turned toward the observer, the edge of the lens which is turned toward the source of light appears in oblique illumination as a glistening white or yellow line by reason of the light thrown back from the interior of the lens and totally reflected at its margin. 4. If the lens is in its normal position or pushed toward either side, by oblique illumination no bright glistening line appears at its margin.

The Treatment of Follicular Conjunctivitis.—Schneller (*Arch. für Ophthal.*, xxxviii, 4) makes the following distinction between trachoma and follicular catarrh: If both retrolateral folds, or a larger part of the conjunctiva, are filled by more than three rows of closely arranged follicles, the diameter of which is greater than a millimetre and a half, and if the conjunctiva between them is densely infiltrated, the disease is trachoma. When the follicles are smaller and fewer in number and the conjunctiva is less infiltrated, the disease is follicular catarrh. This distinction is purely arbitrary and well-nigh useless. For the treatment of the trachoma Schneller recommends a broad excision of the retrolateral fold as soon as the signs of acute inflammation begin to subside.

The Diagnosis of Sympathetic Ophthalmia.—Weiss (*Arch. of Ophthal.*, xxii, 1) believes in the migration theory, but does not believe that the optic nerve furnishes the only route over which the morbid elements can travel to reach the sympathizing eye. If this were true, it would seem remarkable that in the majority of instances the earliest and most pronounced evidences of the disease should first appear in the anterior, and not in the posterior segment of the eye. The statement that the germs commonly enter the second eye at the disc, push their way from behind forward, and, having finally reached the anterior portion of the globe, there for the first time make their destructive influences felt—all this has something problematical about it. As regards the cases of sympathetic neuritis, it is next in order to locate the route along which the infection is carried to the optic nerve. Experiments on animals have dem-

onstrated that it can be transmitted in this manner. When the parts in the anterior segment of the eye are much inflamed, it is difficult, during life, to determine in what percentage of cases the optic nerve entrance and its vicinity are affected; for, even if the ophthalmoscopic examination showed a reddened and ill-defined papilla, the latter appearance may be simply an effect produced by hazy media, and not pathological changes present in the optic disc.

A New Perimeter.—Giles (*Arch. of Ophthalm.*, xxii, 1) has devised a perimeter in which the device for recording observations consists of a graduated index bar fixed at the lower end of a vertical rod, which is connected with the axis of the instrument by means of a beveled gearing in such a way that every change in the position of the graduated arc is indicated by a corresponding change in the position of the index bar. The axis of the instrument is hollow. At the axis is a graduated circle the position of which is fixed, while around it revolve two pointers which are fixed to the arms of the arc. The readings shown on the graduated circle should correspond exactly with those shown upon the chart by the index bar.

The History and Principles of Keratometry; its Value and Limitation in the Correction of Astigmatism.—Weiland (*Arch. of Ophthalm.*, xxii, 1) draws the following conclusions: 1. Keratometry is a very valuable method for the finer diagnosis of the actual construction of the eye. 2. The cornea having been measured, not in the visual line, but in the optical axis of the eye, we find: (a) the direction of the two chief meridians of the cornea; (b) the radii of curvature in these two chief meridians about 1.25 millimetre, or about ten degrees to either side of the corneal point looked at, the result being the more incorrect the more astigmatic the cornea; (c) the cylinder that would correct the corneal astigmatism if placed directly in contact with the cornea, and if the remaining part of the cornea not examined by the instrument does not deviate much from the employed area of the cornea; (d) the cylinder that would correct if placed at the usual distance from the eye. 3. In cases where the corneal astigmatism differs much from that of the whole eye we may then find: (a) the axis of the lenticular astigmatism; (b) the amount of the lenticular astigmatism; (c) the sphere resulting from the combined action of the corneal and lenticular astigmatism.

Embolism of the Central Artery of the Retina.—Elschnig (*Arch. of Ophthalm.*, xxii, 1) makes the following remarks on his series of cases: Ligation of a single carotid artery does not affect vision or produce any marked change in the retinal circulation, since the circulation is at once restored through the medium of the circle of Willis. For this reason, thrombosis of the internal carotid can not directly affect vision. It is possible, however, that thrombosis of the carotid and ophthalmic arteries is a frequent source of embolism of the central artery, for it is difficult to believe that every embolus in a retinal artery has been carried there from the heart. The absence of an embolus in the anatomical preparation does not prove that the clinical diagnosis was incorrect. If some time has elapsed, there may be only a connective-tissue deposit on the intima, which may be covered with endothelium, and escape observation in a casual examination. The centripetal action of the arterial blood current may be explained as follows: The arterial trunk contains an embolus. The blood in its twigs and capillaries, when stasis takes place, is under a pressure not exceeding that of the intra-ocular tension. The neighboring trunk is free and its circulation is normal. A vein of the inferior system anastomoses at the ora serrata with a vein of the arterial twig. As the tension in the arterial twig is less than in the other, the blood flows back into the arterial twig and passes down into the artery, and also out centrifugally into another

arterial branch, the tension of which is also low. The cherry-red color of the macula is partly due to the contrast with the œdematous portion of the retina, but the changes which it undergoes are due to the changes in the pigment epithelium, consisting first in an increase of pigment, and later in its disappearance. These changes in the pigment epithelium are probably not due directly to the retinal anæmia, but to the collateral hyperæmia of the chorioid.

Miscellany.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee.—We are indebted to the secretary, Dr. Frank Trester Smith, of Chattanooga, Tenn., for advance sheets of the abstract of the proceedings of the society's fifth annual meeting, held in Chattanooga on the 17th, 18th, and 19th of October.

The Treatment of Puerperal Mastitis.—This was the title of the paper read by Dr. J. W. Russey, of Chattanooga, who said that compression was of greater general utility, either prophylactic or curative, than any other simple measure; but to be efficient it should be used early after labor. Dr. Guitéras's chest binder was the most satisfactory means of applying pressure. If an abscess formed, the pus should be removed early and perfectly. Washing the abscess cavity was preferable to the use of drainage-tubes. If a drain was necessary, horse hair was preferable to rubber tubing. If circumstances admitted of it, great care should be taken in selecting the point for opening the abscess, as the situation of the scar was of importance from a cosmetic point of view.

The Treatment of the Diseases of the Uterine Appendages.—This was the title of a paper read by Dr. J. A. Goggans, of Alexander City, Ala., who presented specimens of ovaries. The cases reported had all resulted from pre-existing uterine disease, generally endometritis. The three principal points of diagnosis in diseases of the uterine annexa were: 1. Repeated attacks of peritonitis. 2. Repeated hæmorrhages. 3. Pain. The indications for operating were: 1. Those attending peritonitis, accompanied by tortuous and distended Fallopian tubes, which could usually be felt in Douglas's pouch behind the uterus. This condition might be preceded by the history and symptoms of abortion, of gonorrhœa, or of a tubal pregnancy. 2. The physical signs of enlarged and tender ovaries due to chronic abscess. 3. The physical signs of prolapsed and tender ovaries accompanied by irregular hæmorrhages and disabling pains. 4. In some few cases dysmenorrhœa as the principal symptom. 5. Hæmorrhage as the principal symptom accompanied by the ordinary signs of grave pelvic disease. 6. In a few cases general peritonitis preceded by the symptoms of rupture of a pre-existing pelvic abscess, of an ovarian abscess, of a pyosalpinx, or of an abscess developed in the appendages during the progress of puerperal septicæmia. He distinguished endometritis clinically as simple, gonorrhœal, and septic. 7. Constitutional treatment was recommended and it was generally to be followed by local treatment, especially with tampons soaked in a ten-per cent. solution of ichthyol, either with or without previous dilatation of the cervix. This plan of treatment deserved serious consideration before patients were subjected to the dangers of laparotomy.

Membranous Croup, with a Report of Cases treated by Tracheotomy.—R. M. Harbin, of Calhoun, Ga., read a paper which ended with the following conclusions: 1. Membranous croup is almost invariably fatal without surgical treatment, and

with medicinal treatment but little can be hoped for. 2. Any hope from an expectant plan of treatment is nil, and, in view of the few patients that recover without surgical treatment, it does not demand consideration. 3. Tracheotomy is a justifiable surgical procedure, and should be performed in all cases where our therapeutic resources have been exhausted and the patient is in danger of suffocation. In hopeless cases it affords a chance for recovery or promotes euthanasia. 4. Statistics would be better if infectious diseases were eliminated, such as diphtheria, etc. 5. Tracheotomy keeps the patient alive until the false membrane resolves into a muco-purulent liquid and is expectorated through the tube. 6. In all human certainty, the patients whose cases had been reported would have died without the operation. 7. The importance of after-treatment in keeping the tube moistened with limewater and the room at an equable temperature was emphasized. 8. The tube should not be removed until the purulent nature of the sputa ceases, which is about on the eighth day. 9. A lack of instruments is no excuse for the non-performance of the operation, as a tube only is necessary in addition to general operating instruments.

The Treatment of the Omentum in Operations for Hernia.—Dr. G. A. Baxter read a paper on this subject, in which he advocated the removal of the redundant omentum, and reported a case in which four pounds of omentum had been removed. The patient and the omentum removed were shown.

Serous and Watery Discharges during Gestation; their Source and Significance.—Dr. J. R. Rathmell, of Chattanooga, read a paper in which he expressed his belief that the profession had been mistaken in accepting the theory that these discharges proceeded from the amniotic sac. Rupture of the sac was always followed by the expulsion of the fœtus. There were two other sources from which they could come—from the cervix and from the decidua. Cases illustrating these sources were related as having come under the author's observation.

Croupous Pneumonia, with Special Reference to the Prophylaxis and Treatment.—Dr. R. M. Cunningham, of Birmingham, Ala., read a statistical paper on the recent epidemic among the convicts at Pratt Mines. His conclusions were as follows: 1. That the epidemic had been unusually severe, general, and fatal, coming on without apparent cause and practically ending abruptly. 2. That the negroes had been attacked in more than twice as great proportion as the whites. 3. That it had affected all ages alike. 4. That it had attacked the robust and strong as often as those who were in bad physical condition. 5. That it had affected those who worked outside the mines quite as much as those who worked within them. 6. That an unusually large number had been suddenly and violently attacked. 7. That an unusual amount of pulmonary tissue had been involved. 8. That the temperature had been exceptionally high and the pulse and respiration exceptionally rapid. 9. That the mortality had been low considering the extraordinary severity of the endemic and the character of the patients. As a prophylactic measure, disinfection had been tried by washing the cells with a solution of bichloride of mercury and steaming the bedding. The epidemic had terminated abruptly, as a result, the author believed, of this disinfection.

The Treatment of Septic Bubo.—Dr. W. Frank Glenn, of Nashville, read a paper on this subject, in which he advocated the application of ice, the hypodermic injection of a one percent. solution of mercury benzoate, and the use of a compressive bandage. When suppuration had occurred, a free incision was to be made. He thought it would be best to cut out the glands as soon as they became inflamed.

Fractures near the Elbow Joint.—Dr. J. B. Murfree read a paper in which he remarked that it was only rarely that such

fractures were caused by muscular contraction. An excessive or abnormally situated formation of callus and inflammation involving the bones and the soft parts occasionally occurred, and were apt to impair the functions of the joint permanently.

In a paper on the same subject Dr. Willis F. Westmoreland, of Atlanta, said he treated such cases by flexing the arm at a little more than a right angle in a posture of rest. In fractures of the olecranon it was not best to extend the arm fully. He used a plaster-of-Paris bandage.

The Treatment of Biliary Calculus.—This was the subject of a paper by Dr. W. E. B. Davis, of Birmingham, Ala. Speaking of cases in which it was difficult to remove the calculi from the common duct, and the patient's condition would not warrant a long operation, he advocated the introduction of a glass tube with a packing of iodoform gauze about it, without attempting to repair the duct by means of sutures.

Movable Kidney.—In a paper on this subject Dr. J. B. S. Holmes, of Rome, Ga., remarked that an important diagnostic point was the fact that pressure on the kidney always produced nausea and faintness. If there was much disturbance and the kidney could not be kept in place with a bandage or abdominal supporter, it should be removed; but it should first be ascertained if the other kidney was healthy.

The Treatment of Typhoid Fever.—Dr. Y. L. Abernathy, of Hill City, read a paper on this subject. He maintained that in many cases it was impossible to diagnose typhoid fever from continued malarial fever. He believed in an aggressive form of treatment, and advocated the use of quinine and mercury, also hydrotherapy.

Incomplete Ankylosis.—Dr. C. W. Barrier, of Columbus, Ga., read a paper in which he summarized the indications of treatment as consisting of the arrest of the atrophy of the synovial membrane and the restoration of its function by breaking up excessive adhesions and preventing the formation of others, restoring the hamstring tendons to their normal length, and arresting the atrophy of the quadriceps tendon and stimulating it to antagonize the hamstrings. These indications, he thought, were better met by an elastic dressing than by a fixed dressing or an operation.

The Action of Galvanism on the Uterus.—Dr. H. Berlin read a paper reporting the result of certain experiments in which a galvanic current had been passed through the uterine tissue and the latter then subjected to a microscopical examination. In one case the experiment had been performed on the living subject, and the organ subsequently removed. In the other cases the dead body had been used. His conclusion was that the only effect was the destruction of the mucous membrane, and curetting would accomplish the result much more quickly.

At the next meeting, to be held in Atlanta on the second Tuesday in October, 1894, the proposition to change the name to the Southeastern Medical Society will be considered.

Medical Ethics in Washington.—The following article lately appeared in the *Washington Evening Star*:

"There was a largely attended meeting of the Medical Association last evening and the principal business was the hearing of the report of the standing committee. As has been stated in the *Star*, charges had been brought against several members of the association relative to alleged violations of the ethics of the profession, and in accordance with the rules the charges were referred to the standing committee for investigation. The report of the committee was complete, showing that they had thoroughly sifted the charges, and the association indorsed their work by the unanimous adoption of the report. In the case of two doctors charged with practicing homeopathy, the commit-

tee learned that one of the doctors had gone into other business, and that fact itself placed him outside of the association; while in the other case the accused doctor claimed that he had sent in his resignation as a member of the association some time ago and supposed that it had been received. In this case the committee simply reported in favor of granting his request and dropping his name from the rolls.

"The charge preferred against Dr. Hyatt, alleging unprofessional advertisement of himself, was thoroughly disapproved and the committee so reported. As to the charge that Dr. Hammond was making money from a patented medicine of his own invention, the committee, after hearing the evidence on both sides, found that the charge was not sustained. The adoption of the report by the association disposed of all the cases that have been brought to the attention of the association and of the committee.

"It is said that the matter will not end here. The charges were not only unfounded, it is asserted, but publicity was at once given to the matter. It is stated that the proceedings were irregular from the start. According to the rules of the association, charges affecting the conduct of members are to be made in writing and submitted to the standing committee. In this case it is said that the charges were originally made at a meeting of the association by the president, Dr. L. Elliot, who left the chair for this purpose. It is further stated that, contrary to the rules, and on the very next day, the charges were made public in the newspapers before an opportunity was had to have any investigation into their truth. It is asserted as very likely that charges will be brought against the president, and that another investigation will be had."

The New York Academy of Medicine.—The programme for the next regular meeting, on Thursday evening, the 16th inst., comprised the following papers: Myxoedema, Acquired and Congenital, and the Use of Thyroid Extracts, by Dr. George W. Cray; and Remarks upon the Thyroid Treatment of Myxoedema, with a lantern exhibition of photographs of cases, by Dr. M. Allen Starr (to be discussed by Dr. W. Gilman Thompson, Dr. W. K. Draper, and others).

At the last meeting of the Section in Orthopaedic Surgery, on Friday evening, the 17th inst., Dr. Samuel Ketch was to read a paper entitled A Case of Pott's Disease in the Adult, with Paraplegia of Unusual Location and Distribution; Dr. Newton M. Shaffer, one on Three Cases illustrating Relapse after Excision of the Hip Joint; Dr. J. Halsted Myers, one on A Case of Impacted Fracture of the Neck of the Femur; Dr. V. P. Gibney, papers on A Case of Osteitis of the Knee, showing the Correction of a Peculiar Deformity, and on A Case of Supramalleolar Osteotomy for Obstinate Clubfoot.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 20th inst., under the order of Exhibition of Patients, Dr. Walter B. Johnson will show an example of Amblyopia from Suppression of the Visual Image; Dr. J. B. Weeks will show a patient who recovered useful vision after sympathetic ophthalmia which came on forty-two years after the loss of vision in the exciting eye; and Dr. H. Knapp will give a demonstration of an orbital cyst removed *in toto*. Dr. Francis Valk will read a paper entitled The Power of the Interni.

At the next meeting of the Section in General Medicine, on Tuesday evening, the 21st inst., the general subject of discussion will be The Therapeutics of Acute Diseases.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 22d inst., Dr. Horace Clark, of Buffalo, will report several unusual cases, and there will be a discussion on Syphilis of the Upper Air Passages.

Dr. J. E. Nichols will give the clinical notes of cases of adhesion of the velum to the wall of the pharynx from syphilis and other causes.

The anniversary discourse will be delivered before the Academy on Wednesday evening, the 29th inst., at 8.30 o'clock, by Dr. William H. Thomson.

The Horseshoe on the Door.—Dr. T. O. Summers, of Waukesha, Wis., sends us the following:

I wonder where the patients are—
Why everything's so dull;
'Twas just a month or so ago
I had my office full.

But now the bell I never hear,
And money's running low—
I tell you something must be done,
And that right soon, you know.

"I'll tell you what," the good wife said,
"You laugh at old folklore,
But patients stopped that day you took
The horseshoe from the door.

"And I am going to put it back;
You'll see how quick they'll pour
Into your office when you put
That horseshoe on the door."

She put it back and then remarked,
"I told you so before,
And greater men than you believe
In horseshoes on the door."

Alas, for all the luck it brought!
Or patients did restore,
Next day upon my bald pate fell
That horseshoe from the door.

And while I groaned, and bitterly
At superstition swore,
She blandly said, "It brought a case—
That horseshoe on the door."

The Army Medical School.—The following order of duties for the session of 1893-'94 has been issued: Daily, except Saturdays, Sundays, and holidays: 9 A. M. to 12 M., instruction in pathological laboratory; 1 P. M. to 2.50 P. M., instruction in chemical laboratory; 3 P. M. to 4 P. M., lecture. Saturdays: 9.30 A. M. to 10.30 A. M., at Hospital Corps School of Instruction, Washington Barracks, practical instruction in litter and ambulance drill and first aid; 1.30 P. M. to 3 P. M., in Riding Hall, Fort Myer, Va., practical instruction in equitation. The lectures will be delivered as follows: Duties of medical officers, Wednesdays, except November 23, 1893, and January 24, 1894. Military surgery, etc., Thursdays throughout the course. Military hygiene, Fridays, except February 23, 1894. Military medicine, Tuesdays, November 7 and 14, Wednesday, November 22, 1893, and January 24, and Mondays, January 29, February 5, 12, and 19, 1894.

Auxiliary Courses.—Bacteriology, General Sternberg: Mondays to and including January 23, 1894. Military law, Major G. B. Davis, Judge Advocate, U. S. A.: Tuesdays in January, 1894. Comparative anatomy, etc., Captain J. C. Merrill, Medical Department, U. S. A.: Tuesdays in December, 1893. Medical jurisprudence, Dr. Robert Fletcher, F.R.C.S. Eng.: Tuesdays in February, 1894 (except the 27th); also Friday, February 23d. Parasites in man, Professor C. W. Stiles, M.D., Department of Agriculture: Tuesdays, Novem-

ber 21 and 28, 1893. Due notice of any change of programme will be posted on the bulletin board.

[Signed.] WALTER REED,

Captain and Assistant Surgeon, U. S. A., Secretary of the Faculty.

The Emergency Treatment of a Toothache.—In the *Medical Record* for November 11th Dr. John E. Weaver, of Rochester, writes to the following effect: Toothache, according to the books, is a matter of small consequence, but many a physician would rather meet a burglar at the door on a dark night than a call to cure a bad toothache of several days' continuance. A hypodermic injection of morphine only postpones the evil day, and usually the patient is respectfully referred to the dentist. The tooth should not be extracted while the jaw and gums are inflamed and the latter swollen, and it is the physician's duty to treat the case until these conditions are removed. The author advises always keeping on hand a small phial containing a mixture of ten drops each of chloroform, glycerin, and a saturated solution of carbolic acid and a grain of morphine, also a small wad of absorbent cotton. If the aching tooth has a cavity or a decayed surface, a small pellet of cotton should be saturated with the mixture and put into the cavity or against the decayed surface, as the case may be. The cotton is not to be packed in, for it will increase the trouble, but the pellet should be small enough to enter without crowding. In most cases this will end the trouble. When the gums are swollen and tender they should be painted two or three times at intervals of two minutes with a four-per-cent. solution of cocaine. At this time of the year, the author remarks, the patient may have been eating a good deal of fruit. If the tongue and the mucous membrane of the mouth are pale there is probably sour stomach, and the next day the toothache will return. Under such circumstances ten grains each of bismuth subcarbonate and phenacetine should be given at once before each of the three following meals, with a laxative if needed, and the eating of fruit should be stopped for a few days.

The Medical Society of the University of Maryland, which was recently organized in Baltimore, to be composed of the faculty, the adjunct faculty, the members of the teaching and hospital staffs, and graduates of the university, will meet on the first Tuesday of each month. The officers were elected as follows: President, Dr. J. J. Chisholm; vice-president, Dr. C. W. Mitchell; secretary, Dr. W. B. Canfield; members of the executive committee, Dr. J. E. Michael, Dr. W. B. Platt, and Dr. J. M. Hundley.

Sore Nipples.—The *Medical Report* recommends the application of a mixture of four parts of ichthyol, five parts each of lanolin and glycerin, and ten parts of olive oil, which is to be washed off before the infant is allowed to nurse.

Kerosene-oil Poisoning.—In the *Indian Medical Record* for October Dr. John Morton, of Mussoorie, relates the following history of a case:

"An old retired officer of the educational department, who has been under observation for insanity, in a fit of temporary mania swallowed half a bottle of kerosene oil, and immediately afterward, finding the effects of the oil too depressing, took two ounces of sal volatile. On seeing the patient two hours after this accident, I found him collapsed. His lips were blue, and face generally cyanosed. The pupils were dilated, and he complained of great difficulty in swallowing. Under his bed lay a good deal of blood which he had both vomited and coughed up. From the severe vomiting, I judged that very little of the oil had remained in his stomach, and therefore did not think it necessary to give him an emetic. As there is no

recognized antidote for kerosene oil, I treated him on rational principles, allaying the extreme sickness by bismuth and soda, and warmth to the body. For some days the dysphagia continued with rawness of the throat. He occasionally vomited the nourishment given him in teaspoonfuls, but with the addition of a little opium to his mixture, these symptoms subsided. There was no diarrhoea at any time. The kidneys were probably congested for a week afterward, the urine being passed in very small quantities. He did not quite recover for a month later, but he seems now to have entirely regained his health and strength. For the dysphagia I used cocaine lozenges with great benefit."

The Strychnine Treatment of Snake-bite Poisoning.

Dr. Mueller, of Australia, the champion of the use of large doses of strychnine in the treatment of snake-bite poisoning, has recently published a book entitled *Snake Poison, its Action and its Antidote*. In the September number of the *Australian Medical Journal* there is an editorial article on the subject of which the following is the concluding portion:

"At the outset, Dr. Mueller must be congratulated on the ingenuity with which he conceived his theory, and the energy and eloquence with which he advocates it. His analysis of the symptoms produced by snake poison, and the conclusions drawn as to its mode of action, and the consequent antagonism existing between it and strychnine, are deserving of the highest praise. It must be conceded that some antagonism does exist, as shown by the large doses of strychnine tolerated by snake-bitten persons. The contention, however, that strychnine is a complete antidote does not appear quite sustained at present, and Dr. Mueller's refusal to admit the results of experiments on animals is not only unscientific, but illogical. He appeals to Feokistow's experiments on animals to confirm his views as to the action of snake poison, but refuses the same experimenter's results as to the action of strychnine.

"Then again, as above stated, when strychnine fails in the human subject, the failure is attributed to the faulty method of its use—it was not given in sufficient quantity, or was given too late. On the other hand, when we remember how exceedingly difficult it is to estimate the amount of snake poison actually received by bitten persons, and the liability to confuse the symptoms produced by fear, or by alcohol, with those of snake-poisoning, it is evident that the value to be attached to cases of recovery must be largely discounted. It is always possible that recovery would have taken place had nothing been done. Hence we must fall back on the experimental method; and at the last meeting of the Intercolonial Medical Congress Dr. C. J. Martin, of Sydney, was appointed to investigate whether strychnine is an antidote to snake poison, and the results of Dr. Martin's experiments will be awaited with much interest."

The late Dr. Clarence Glisan, of Portland, Oregon.—The following resolutions were adopted at the last stated meeting of the Society of the Alumni of Bellevue Hospital:

Resolved, That it is with the deepest regret that this society has learned of the death of Dr. Clarence Glisan, one of its younger members, who had entered upon a career of honor, usefulness, and success.

Resolved, That in the death of Dr. Glisan his colleagues have lost a friend endeared to them by his noble qualities of heart and mind.

Resolved, That this society, in expressing its sorrow and appreciation of its loss, desires in addition to extend its deep sympathy to his bereaved family.

THE EXAMINATION UNDER ANÆSTHESIA: ITS USES AND ITS LIMITATIONS.

By HOWARD A. KELLY, M.D.,
PROFESSOR OF GYNÆCOLOGY AND OBSTETRICS IN THE
JOHNS HOPKINS UNIVERSITY.

THE examination under anæsthesia has a broad field of utility as yet not fully realized in gynæcological work. In this way alone are we enabled to palpate the whole peritoneal surface of the uterus, anterior as well as posterior, together with the ovaries and the tubes. If the patient be highly sensitive, if there be tympanites, or if the abdominal walls are thick and vaulted, it may be impossible to exclude the presence of myomata and lateral inflammatory disease by the usual methods of examination, and the utmost the gynæcologist will be able to affirm in his note will be "tenderness," or "sense of resistance in the fornices," or "probable pelvic inflammatory disease." The examination under anæsthesia at once answers the query completely and satisfactorily as to "neurosis" or "inflammation" or "tumor." I have thus repeatedly found disease calling for immediate operative treatment in patients who had been examined in the ordinary manner, and had even been treated topically.

A want of familiarity with the methods and a failure to employ anæsthesia for purposes of examination may be a source of grave error in gynæcological diagnosis.

Chloroform is, as a rule, the best anæsthetic for this purpose, on account of its rapid action, and the fact that it is not so apt to be followed by nausea and vomiting.

Frequently the patient can be examined under the primary effect of the anæsthetic in less than a minute, even noting during the examination the smallest irregularities

FIG. 1.—Corrugated tenaculum for catching the cervix and holding the uterus down near the outlet. The corrugations prevent the tenaculum from slipping while it is held on the ball of the thumb by the third and fourth fingers. The index finger of the same hand may be used in making a rectal examination. This practically makes two hands out of one, leaving the other hand free for the abdominal palpation.

of surface in uterus or appendages, and detecting the slightest adhesions.

The Manner of conducting the Examination under Anæsthesia.—The patient is brought to the edge of the

FIG. 2.—Traction forceps employed in drawing the uterus down toward the outlet.

table; her thighs are well flexed on the abdomen and held in this position by an assistant on either side, or by Kelly's leg holder.

The index finger is first introduced into the vagina to determine the position of the uterus. A bullet forceps,

FIG. 3.—Cervix drawn down into artificial descensus to vaginal outlet by means of corrugated tenaculum. Bimanual palpation of anterior surface, fundus, and posterior surface through rectum and anterior abdominal wall.

or the author's corrugated tenaculum (Fig. 1), is then introduced on the index finger and the anterior lip of the cervix caught. The tenaculum is held by one of the assistants while the examiner introduces his finger into the rectum, and with the other hand pressing down through the superior strait makes a thorough bimanual examination. Instead of the corrugated tenaculum, the bullet forceps which is used in repairing the lacerated cervix may be employed as a tractor in drawing the uterus into descensus (Fig. 2).

In order to reach the fundus uteri and the ovaries and tubes it is necessary for the assistant to draw the cervix down, sometimes even as far as the vaginal outlet (Fig. 3).

With the uterus thus brought into artificial descensus the examiner will be able with perfect ease to palpate its fundus, and upon pulling the uterus over into retroflexion, by hooking the rectal finger over the fundus, the whole anterior surface as far as the bladder is brought within touch (Fig. 4).

The ovaries are readily found by taking the utero-ovarian ligaments as landmarks; these are always felt as distinct sharp cords in the posterior surface of the broad

ligament just below the cornu uteri; by following them out for an inch from the uterus the ovary is found. In this way the identity of doubtful bodies lateral to the uterus

FIG. 4.—Uterus drawn down into artificial descensus to vaginal outlet and into retroflexion by means of the rectal finger hooked over the fundus, thus bringing all of its surface into easy touch.

is often determined, and ovaries apparently impossible of access are readily palpated.

Such an examination as this is but rarely possible in the conscious subject. The extreme displacement here spoken of is not injurious if traction is not made when more than slight resistance is encountered. This displacement must not be kept up for many minutes, and must not be repeated too frequently.

The Indications for the Examination under Anæsthesia.—

1. In a young woman with an intact hymen.
2. When the ordinary vaginal examination is not satisfactory, leaving the question as to the condition of the appendages and the fundus uteri in doubt, provided—
3. That the patient's history and symptoms indicate an intrapelvic affection.
4. That the examination is made by a trained and gentle hand.

The fourth condition may be modified, however, in case of necessity, as any physician possessing a good general idea of pelvic diseases ought to be able to exclude the presence of serious intrapelvic lesions in the absence of resisting masses which are evident even to an untrained touch.

Nota Bene.—There should be no undue haste in proceeding to an examination under anæsthesia where the

symptoms are not urgent. It is also often best to first test temporizing measures in cases which may be kept under observation.

The Limitations in the Employment of the Examination under Anæsthesia.—1. Unnecessary examinations must not be made; in the majority of cases an ordinary thorough vaginal examination, if conducted with a little tact and persistence, or, if necessary, a second examination at a later date, will afford sufficient information to direct the treatment.

2. Patients must never be examined without their full consent, and they must have the right to withdraw their consent at the last moment.

3. Great care must be taken in examining young girls. In no case should the hymen be ruptured except under stringent necessity. An index finger larger than six centimetres in circumference debars its possessor from the right to make a vaginal examination in young women even under anæsthesia. The preservation of this mark of her virginity is the sacred, inviolable right of every unmarried woman. The careless rupture of the hymen to secure information which can be as well or better gained by a rectal examination is an outrage. Even when it is necessary to dilate the cervix this can be done by catching the cervix with a forceps introduced into the vagina and guided by the rectal finger; in this way the uterus can be drawn down within reach, while the hymen is held gently open by a virginal speculum.

4. No respectable unmarried woman should be used for class teaching. To place a virgin on the table under an anæsthetic at the disposal of a class of students is a defilement closely akin to rape, revolting to every honorable instinct.

5. Patients with tumors and pelvic inflammatory diseases should not be kept anæsthetized over half an hour, and never more than three physicians should be allowed to examine a patient under one anæsthesia.

6. These examinations must be made with great gentleness and under the direction of a responsible teacher, as rough examinations often rupture pus sacs, hæmatomata, and large cystic ovaries, or bruise the abdominal walls.

7. After such an examination the patient should rest for some hours, or even for several days in bed.

8. These examinations must be conducted in privacy, but few students being admitted to the room at a time.

9. Out of respect to the patient, visitors should not be permitted to come and go from the examining room during the examination.

I have advocated strongly the importance of systematic examinations in doubtful cases under anæsthesia, and have endeavored to pave the way for a general adoption of this plan in my paper on *The Examination of Normal Ovaries*.* I have thus been at pains to lay down these explicit rules with regard to its limitations as I have perceived their urgent necessity in several instances.

* *American Journal of Obstetrics*, February, 1891.

INTESTINAL OBSTRUCTION FOLLOWING ABDOMINAL SECTION.*

By L. H. DUNNING, M.D.,
INDIANAPOLIS, IND.

OF the complications following abdominal section few are more fatal than occlusion of the intestines. It may appear in a few hours after the section, or not until several weeks have elapsed.

I shall treat only of acute intestinal obstruction in this paper. It is difficult—indeed, well-nigh impossible—to form a just estimate of the frequency of this occurrence. The writer is conscious of having met with but a single case in one hundred and thirty abdominal sections, yet this case, occurring two weeks and a half after what we had considered a very successful ovariectomy, the first symptoms of which appeared on the first day the patient sat up, has made a deep impression upon his mind and has led to the writing of this paper. The occlusion of the intestines may be caused by torsion of the intestines, invagination, by internal strangulation of some portion of the tract in consequence of a loop of intestine running through an opening made by a tear in the omentum or mesentery, by acute flexion of the intestine induced by its adhesion to some portion of the internal abdominal wall or to some abdominal viscus, by compression of a portion of the intestine in consequence of adhesion stretched over it and pressing upon it, by internal strangulation resulting from incarceration of a portion of gut after having extended through a foramen formed by adhesive bands or by adhesion of a loop of intestine, the mesentery and intestine forming a considerable portion of the circumference of the foramen. Invagination is most frequently found in the small intestines and is not more prone to appear after laparotomy than at other times. It is surprising that torsion does not more frequently occur after abdominal section. The reasons are, I think, that the sigmoid flexure of the colon where it is most prone to appear is not often disturbed during the section, while the peristaltic movements of the intestines and the method of attachment of the mesentery prevent anything more than a temporary torsion of the small intestines. The movements induced by the respiratory effort also have a tendency to restore the displaced small intestines to their normal positions. Rude manipulation of the omentum and mesentery sometimes results in tears, leaving an opening which may lead to future trouble.

In Rockwell's table of eighty-nine cases of acute intestinal obstruction,† twenty-four, or thirty-four per cent., were due to adhesions. A larger percentage of instances of occlusion will be found due to this cause in cases following abdominal section.

The symptoms to which this occlusion gives rise are usually pronounced at first, but may in case of internal strangulation not appear in all their intensity until the second day. Persistent vomiting is almost always present.

At first the matter vomited may be simply undigested food, or the liquids drank, but later will be of a bilious character, and further on stercoraceous. This vomiting is uncontrollable. There is always pain, which is usually at first localized about the site of obstruction, and finally is more or less general. There is frequently localized tenderness situated according to the site of the occlusions. Except in cases of invagination, tympanites is almost constantly present. When the occlusion is in the small intestines, which it more frequently is, there may be during the first few hours a faecal passage, but later on no thorough action of the bowels can be obtained. Occasionally there may be a passage of flatus, but it will be from the large intestines.

Obstinate constipation and persistent vomiting must be taken as the most characteristic symptoms, and if stercoraceous vomiting occur it is pathognomonic of occlusion. One can not fail to observe the appearance of the countenance, which indicates the presence of a grave lesion. The pinched expression, the sunken eyes, around which are dark circles, all betoken a serious malady. The temperature is sometimes elevated, though in many of the gravest cases it does not reach higher than 102° F. So far as my observation has extended, the patients are always aware of the gravity of their illness. At the last a condition of collapse appears, and usually delirium is present the last few hours. The malady is uniformly fatal if the occlusion is not overcome by surgical means. The early diagnosis of the case is of the utmost importance, and yet is often difficult. The occlusion that appears many days or several weeks after the section usually is attended by symptoms that lead to a suspicion of adhesions.

The following is a history of my case, which will illustrate this point:

Mrs. D. was operated upon June 26, 1893, by abdominal section for the removal of a twenty-five-pound ovarian tumor. There was a history that indicated the rupture of the tumor into the peritoneal cavity some time previously. She was examined by Dr. Sweeny, of Milton, Ind., who discovered an ovarian tumor reaching above the umbilicus. A few days later the patient felt a sudden giving way, and this was followed by a gradual disappearance of the tumor. Two weeks later she came to me for examination, when I could find no evidence whatever of an ovarian tumor, but there was ascites. Several months later she came to me again, when, on examination, I found a somewhat movable fluctuating tumor as large as a seven months' pregnancy. On opening into the abdominal cavity, a quart of thick, gelatinous fluid ran out of the wound. The tumor was found adherent to a loop of small intestines and to the parietal peritonæum upon the left side. The pedicle was attached to the left side and was made up of the ovarian ligament and a portion of the left broad ligament. It was short and broad as three fingers and was secured by a ligature and cut off just above the same. The cyst was multilocular and contained about three gallons of thick, glossy-like semi-fluid of the same character precisely as that found in the abdominal cavity, except that it was slightly thinner. The abdominal and pelvic cavities were irrigated and a careful toilet made. No drainage was used. There was nothing very unusual in the course of the case subsequent to the operation except that she had more difficulty in obtaining an action of the bow-

* Read before the Mississippi Valley Medical Association at its nineteenth annual meeting.

† *Annals of Surgery*, vol. viii, p. 91.

els, and that she was troubled by an accumulation of gas. On the seventeenth day she sat up in a chair. For a week she had been importuning us to allow her to leave the bed. She was strong and apparently well, except that she complained of pain in the right inguinal region. Her bowels moved in the morning as a result of an enema. In the afternoon she sat up half an hour and seemed to enjoy it; after lying down she complained of considerable pain in the lower part of the abdomen. An enema was given and she had a good movement; also emitted gas. The pain continued and in a few hours she vomited. Codeine and bismuth were given. There was a slight elevation of temperature and the pulse reached 90 per minute once; at other times it was 84 per minute. The following morning showed the patient restless, with occasional vomiting, but no tympanites. The temperature rose gradually during the day and finally reached 101.4° with a pulse of 96. The vomiting was persistent. High injections were used; the first one resulted in a small movement and the passage of considerable gas. Small doses of calomel, and finally Epsom salts, were given, only to increase the urgent symptoms. The vomiting was of a watery fluid and bilious later. The following morning the symptoms were still more urgent. The vomited matter was grumous, and about nine o'clock (forty hours after onset) it became stercoraceous. There were tympanites, considerable pain through the abdomen, and persistent constipation. There could be no doubt there was complete occlusion. We determined to reopen the abdomen, but the delay in the arrival of the patient's husband compelled us to defer the operation until several hours later. It was done at 2 P. M.—forty-five hours after the onset, and about twelve hours after we became convinced there was complete occlusion. The section was made through the former incision, which was firmly united. We came at once upon a largely distended small intestine of a chocolate color. Pushing it to one side, we found about eighteen inches of collapsed small intestine; finally, in the right iliac fossa we found a foramen into which a loop of intestine had passed and had become strangulated. This foramen was formed by an adhesion of a loop of the small intestines to the stump; this loop was slightly rotated and fixed so that in addition to its mesentery it formed a large portion of the wall of the foramen; the stump, head of the colon, and adhesions formed the remainder of the wall. The opening was large enough to readily admit the index and the middle fingers. The adhesions of the intestine to the stump were easily broken up, and thus was the strangulated portion of the intestine set at liberty. The collapsed portion, which had been pale, gradually distended with gas and took on a rosy color. The intestines were replaced, the omentum drawn down over them, and the abdominal incision closed. The patient suffered much from shock and we were energetic in our effort to relieve her. The bowels acted before the patient left the table. After placing her in bed the stercoraceous vomiting continued and the evidences of shock continued. The patient died three hours after the completion of the operation. A more favorable result might have been expected had we operated earlier, though the reported cases show a very high rate of mortality.

The question of prophylaxis is a most important one. Rude handling of the omentum and mesentery should be avoided. When a tear in either of these structures is observed it should be at once closed, or, if in the omentum, a portion of that structure may be incised and the edges of the incisions stitched together with fine silk. Adhesions are most liable to occur in cases in which there have been found many adhesions at the time of the operation, in in-

stances in which the peritonæum has been abraded, the hot iron or chemical agents have been used, and, lastly, in cases in which septic material has been introduced during the section. The utmost care should be employed in separating, so far as possible, all adhesions formed, and in closing in abraded or incised surfaces by stitches or omental grafts. Many times this will be impossible. I believe the use of the hot iron and chemicals within the abdominal cavity has been sufficiently often and forcibly condemned to make their use infrequent. Hereafter I shall endeavor to cover the cut surface of the stump by uniting the peritoneal edges by sutures. This can be readily done if the stump is left moderately long and a wedge-shaped piece removed from the center. It is unnecessary to dwell upon the advisability of avoiding the introduction of septic material during all operations. We all understand the importance of this, and endeavor to obtain a clean record in this regard. Much discussion has arisen during the last two or three years regarding the effects of the abdominal bandage in favoring the occurrence of intestinal obstruction. There can be no question but that the binder limits the movements of the intestines, and thus it may to some extent favor the formation of adhesions, if there be exposed abraded or cut surfaces.

I do not, however, believe we are justified in abandoning the use of the binder, for the reason that, in case of a large tumor, it yields a support to the abdominal organs and blood vessels that gives comfort to the patient and may and often does prevent shock, internal congestion, or hæmorrhage. It, too, renders the occurrence of ventral hernia less frequent. That there is a tendency to the harmful habit of wearing it too tight after the first few weeks, and to wear it too continuously, there can be no doubt. Frequent turning of the patient upon the side after the section has been recommended. It appears reasonable that this would tend to prevent adhesions, and I am now in the habit of having the nurse turn the patient upon the side, where she can lie as long as comfortable, commencing twenty-four hours after the operation is completed. Some patients will not tolerate this, but with many it is a source of comfort. I have observed no ill effects following the procedure.

Massage has also been recommended in cases where the pain is persistently localized at the same point, and there is a suspicion of the formation of adhesions. I doubt not this might be beneficial in some instances, yet the employment of this method must favor the separation of the incision and tend to induce ventral hernia, and I would fear its harmful influence if there were localized peritonitis. An early action of the bowels results in benefit to the patient in so many ways that I have sought to obtain one in all cases, unless it is specially contraindicated. Not the least of these benefits is the prevention of adhesions. When all the precautions I have mentioned are adopted, intestinal occlusion will not often occur. The question of the administration of cathartics in cases of suspected or threatened occlusion is one oftentimes difficult to decide. Under such circumstances, I am inclined to the belief that during the first week after section cathartics are indicated, and I pre-

fer to administer one-grain doses of calomel every hour for a few times, then to administer doses of Epsom salts every two hours until an action is obtained or it is demonstrated that a harmful effect is being produced. Several times during the last year we have been enabled to overcome difficulties that seemed grave and threatening to the life of the patient because of temporary occlusion. In one instance the patient had been condemned to operation or death. High injections and opium had been used to no avail; calomel and sweet oil induced an action of the bowels, and a prompt recovery of the patient took place. When it is demonstrated that complete obstruction is already present, of course cathartics are harmful; then high injections of hot water or gas may be tried; but little can be expected of them. Opium may be indicated for the relief of pain, but can effect nothing in the way of overcoming occlusion of the bowels following abdominal section. In this malady the vast majority of patients will die, unless resort is early had to reopening the abdomen and removal of the cause of the obstruction. Even with such active interference the majority of the patients will die. It, however, affords the patient the greatest chance of recovery. No specific directions can be given as to the method of procedure on reopening the abdomen. A distinct understanding of the pathological conditions possibly present must guide the operator in his search for the cause of the occlusion, and, when found, it should be dealt with in the shortest possible time consistent with the permanent cure of the patient.

A NEW AND NON-OPERATIVE METHOD OF TREATING DYSMENORRHEA, PELVIC INFLAMMATION, AND PELVIC ABSCESS.*

By T. J. MCGILLICUDDY, A. M., M. D.,

SURGEON TO THE NEW YORK WOMEN'S HOME MATERNITY HOSPITAL;
CONSULTING PHYSICIAN TO THE ITALIAN HOSPITAL, ETC.

Not only less and better surgery but more radical therapeutics should be the aim of all modern gynecologists. The therapeutics of gynecology is practically limited to the application of boroglyceride tampons and the ordering of hot vaginal douches, along with a few other minor measures; and standard works on medical gynecology are comparatively few in number and rather disappointing in their contents. They seem to be seldom utilized by the profession, and are probably relegated to the top shelf of the library. The so-called conservatives, while decrying excessive zeal in surgical interference, seem to have done little or nothing to offset it, but have simply taken their fees in many cases without giving the patients much, if any, appreciable benefit.

This subject of medical gynecology is revived for the purpose of bringing forward and emphasizing the importance of a therapeutical resource that has hitherto, so far as I am aware, been unknown or entirely neglected—viz., the depletion of the vessels of the pelvis in inflammatory conditions, first, by the stimulating action of hot water taken

in rather large quantities on an empty stomach, and, secondly, by the ingestion of a large amount of properly prepared and easily digested nitrogenous food, with a partial abstinence from that which is starchy and saccharine. This might be termed the dietetic treatment of pelvic disease, but it is more than that.

I also give in the subacute and chronic cases, when indicated, the citrate of iron and quinine, and sometimes also Fowler's solution. The latter I find here of special benefit as a strong nerve tonic. It gives tone to the arteries of the uterus, a lack of tone being often a great factor in producing the original disease. Where the appetite and digestion are poor, I order a dozen drops of dilute hydrochloric acid in a glass of water immediately before meals.

The effect of the hot water is to stimulate not only the portal and systemic veins, but also the lymphatic system, and by absorption and endosmosis cause the removal of congestions and inflammations within the pelvis. Exudates and lymph before its organization are absorbed by this process, and, if the inflammation is plastic and not suppurative, the absorption goes on very rapidly. The pus corpuscles, when present, become granular, disintegrate, and are, I believe, absorbed; at any rate, they disappear in most cases along with the inflammation. The improvement in the venous and lymphatic circulation produces a continuous beneficial effect, which in these cases is a great advantage over the intermittent and astringent action of hot vaginal douching and boroglyceride tampons. These local measures may be combined with the hot-water treatment if it is thought necessary.

The effect of a proper nitrogenous diet is to feed and strengthen the heart muscle (which here, indeed, acts as a pump to the congestion) as well as the muscular fibers of the blood vessels and viscera, and, as a consequence, the circulation in the systemic venous system and its appendage—the portal vein—is stimulated. Sometimes, as an intestinal antiseptic, tablets of one one-hundredth of a grain of the bichloride of mercury are very useful, and bitter tonics should also be given if indicated. If there exists, as is usual, stomach and intestinal catarrh, with fermentative dyspepsia, rhubarb-and-soda mixture, in teaspoonful doses, should be given two hours after meals. Before meals, taken in water, it is an excellent detergent, and acts as an artificial bile to the irritated mucous membrane. A few drops of the fluid extract of *hydrastis canadensis* in water is also beneficial. As a vaginal astringent the white extract of *pinus canadensis* should also be used on tampons, or a solution containing five grains each of alum and sulphate of zinc to the ounce of water, with a little glycerin added.

A very advantageous supplementary measure consists in douching the whole of the colon twice daily with a very large quantity of hot water. It is administered from a fountain syringe while the patient lies quietly on her back, resting upon an inflated surgical cushion that drains the water off one side into a receptacle. These colonic flushings are also exceedingly useful in nephritic colic, threatening appendicitis, and many other abdominal diseases. This flushing not only promotes cleanliness by its mechanical effect, but acts as a stimulant by increasing the volume of

* Read before the New York State Medical Association, October 12, 1893.

the circulating fluid, and hence the general vascular tension, and at the same time excites the emunctories to greater activity. If the intestine be flushed with a bland fluid, such as water, most of it is eliminated from the system by the kidneys, as is shown by the increased frequency of urination after such injections. When water is taken by the mouth, if it be not saline, it is almost entirely absorbed.

This method of relieving pelvic congestions has other great advantages; it often removes with remarkable rapidity morbid conditions of the blood and actual structural disease of important organs, such as the stomach, kidneys, heart, and lungs. Many persons are in a state of apparent health, and yet the blood may be so vitiated and full of morbid materials that they are at any moment liable to serious acute disease and to the development of chronic visceral disease. Those who are overloaded with degenerate fat are typical of this class, and here especially this method is of advantage. To women otherwise of sound constitution and good habits, whose diet and hygienic surroundings are of the best, this treatment, properly given, will certainly do no harm, if it does not always remove the local disease. To those whose physical powers have been impaired by excesses or exhausted by labor and anxiety or by scanty and improper diet, and whose nervous systems have been irritated by an excess of stimulating food and drinks, it is of the greatest value. After a course of this treatment under proper hygienic conditions and a freedom from the anxiety of a struggle for daily bread, the pelvic disease rapidly disappears unless the case is one where an operation is absolutely necessary. In that event the patient is in good condition to undergo even the most serious operation with the best prospect of rapid wound healing and freedom from complications.

Let the reader remember the vascular supply and the physiology of the liver and the pelvic organs, and especially the entero-hepatic circulation, or the portal system; it is then easy to see how the greater number of diseases of the uterus, tubes, and ovaries can be relieved in this way. Other means, however, as adjuvants, should not be neglected, and to accomplish these results time, skill, and patience are requisite. Its field of application is in those border-line cases now so frequently operated upon, such as dysmenorrhœa, salpingitis, ovaritis, ovarian and hysterio-epilepsy, ovarian neuralgia, pelvic cellulitis, and pelvic abscess; cases of large cystic or fibroid tumors and cancer are not, of course, in any way benefited.

No one who has not tried this method correctly and faithfully can have any idea of its value in chronic disease; and, like the great painter who mixed his paints "with brains, sir," one must bring his common sense to bear strongly on the subject, and be free from prejudice which is generally begotten of ignorance. I have absolutely demonstrated its great value by a long series of clinical cases. The whole method simply consists in assisting Nature to perform the cure physiologically—i. e., by pelvic venous absorption.

Every physician is or ought to be familiar with the extremely intimate relationship of the digestive and pelvic organs and their mutual interdependence. There is every

reason why the gynecologist should be a well-seasoned physician and that the intimate connection between internal medicine and pelvic disease should be thoroughly appreciated by him. It sometimes seems almost as though medicine was divided into too many specialties. The true specialist must, above all, be a first-class general practitioner; if he is not, he may be well termed a *pseudo-specialist*.

The fact that the body should always be treated as a whole is shown when we know that all the internal organs in the abdominal and pelvic cavity have a common vascular and nervous supply, so that when one of these organs is diseased those that are intimately connected with it suffer at the same time. If one will but think of the intimate connection of digestion with pregnancy and menstruation and the great influence that disturbances of the stomach and liver have upon the uterus and its annexa, and that we never have weakness of one organ without weakness of all, when the weakness is due to deranged nutrition, we can then readily see the intimate connection between the uterus and the digestive system. We should also remember that the blood supply of all these organs being more or less a common one, venous congestion in all of them generally depends upon obstructions in the portal circulation. This is proved clinically in a great variety of instances. Take, for example, a young girl with anæmic dysmenorrhœa. This is wholly dependent on improper assimilation of healthful food, and in the majority of cases the diet and digestive organs are at fault. In cases of hepatic obstruction there is always portal congestion with accompanying chronic metritis, endometritis, pelvic congestions, and leucorrhœa. The same condition may take place when the heart muscle is weak from lack of nourishing nitrogenous food to strengthen it. The digestive tube, with its twenty-seven feet of length, is by far the most important organ in the body, and the moment it becomes irritated and coated with catarrhal mucus the patient begins to suffer.

These catarrhal states of the gastro-intestinal tube are probably the most common pathological condition existing. Catarrh seldom limits itself to one portion of the tract; it generally extends by continuity from the stomach upward to all parts of the nasal and pharyngeal mucous membrane and downward through the intestines to the rectum, and yet often gives but slight warning of its presence. The common term for it is chronic gastro-intestinal catarrh, but a far better one, because truer and more comprehensive, is the old-fashioned one of "catarrhal diathesis."

Most cases of dysmenorrhœa in young girls are dependent on portal congestion and anæmia. Some noted gynecologists deny that endometritis occurs in young virgins from flexions and stenoses retaining the secretions and causing their decomposition, thus inflaming the lining mucous membrane. They are undoubtedly correct, as there is nothing to prevent the liquid blood flowing away, and there is in reality no cavity to retain it.

We must not forget that the liver, which is a most elastic organ, can also be utilized as a muscular pump to draw up the blood through the portal system from the whole pelvic region, and while we are using astringents or

applying tampons soaked with glycerin for its hygroscopic effect, we should also remember that we can get a similar result in the opposite direction by draining the serum and blood from the affected parts through the agency of the intestines and the portal circulation. In these conditions the injection of a small quantity of sulphate of magnesium into the rectum is sometimes very useful. In most cases of chronic metritis and endometritis the condition is very much like that in the rectum when piles exist, and the treatment may be to a certain extent the same or similar.

I am not a believer in the treatment of uterine diseases by excessive drugging; still, I am thoroughly convinced that medical gynecology has been sadly neglected for some years past, and that our next great advances in medical science will include this department.

The uterus is a sensitive organ, and the overdistention of it by dilators for a stenosis which never existed except in the mind of the operator, and the correction of flexions which are normal, the application of strong acids to the interior of the uterus, inflaming its delicate membrane and sealing up the utricular glands, do a good deal toward the production of disease and sterility. Endometritis existing alone is a rather rare condition; it is generally accompanied by salpingitis, pelvic cellulitis, or metritis. If these are removed, the endometrium generally takes care of itself without any local applications. Where the endometritis depends upon vaginitis, this must first be removed before the endometritis will disappear. Unnecessary and unskillful treatment of the endometrium has been the cause of some abdominal sections. We should look at endometritis from above and consider the portal circulation and see if some of the congestion and inflammation and drainage can not be diverted in that direction and removed through that channel.

Almost all ovaries on the post-mortem table look more or less diseased. Of this I have had abundant evidence in the deadhouse on Blackwell's Island. Although simple serous cysts are of extreme frequency, there is still always plenty of sound tissue remaining, showing how the organ could still perform its function normally.

When the operation for the removal of a diseased organ is a dangerous one, as celiotomy always certainly is, in spite of good statistics and brilliant operators, the disease should be incurable by ordinary means and the patient a chronic invalid before the operation should be performed.

The following case is typical and interesting in this connection:

Mrs. L. M., aged twenty-eight years. Pelvic disease came on with a severe chill and fever after her first labor, which was tedious and instrumental. I first saw her several months after this. She was then extremely enfeebled, emaciated, anæmic, and nervous, and had about lost all hope of recovery. She was suffering from frequent attacks of very severe pelvic pain, requiring repeated hypodermics of morphine. Menstruation was absent.

On digital examination, a very tender, throbbing, and boggy tumor was found to the left of the uterus. It was larger than an orange, and fluctuation could be distinctly felt. It could be easily examined through the abdominal wall, and caused great irritation and depression. The result of the treatment by the

hot water and diet, no colonic flushings being given, was to completely relieve the pain and inflammation and to cause absorption of the pus and exudation with the exception of some slight thickening. What gave her the most joy after the removal of the painful attacks was the painless return of her menses after a period of seventeen months, although her baby had always been bottle-fed.

Her recovery was rapid and complete, she being under treatment for less than three weeks. Her physical condition became entirely changed. She had been told by two surgeons that only an operation would relieve her condition, but she declined operative interference.

There can be no question in the mind of any thoughtful physician that galvanism, as recommended by Dr. E. Sanders for the indurations following pelvic cellulitis, is an efficient means of treatment for that condition. His valuable contribution on this subject can be found in the *American Journal of Obstetrics* for March, 1892.

Our advances in abdominal surgery have been marvelous, but we should be careful not to step too far. For the benefit of any who may have forgotten some of their pathology, learned in college days, I would remind them that there is such a thing as the physiological reabsorption of pus. This may be incomplete by a cheesy change or inspissation, and this is a common process, pus being more watery than blood. When complete, the pus entirely disappears after undergoing a fatty metamorphosis or emulsion. Pus is never reabsorbed as pus, but is broken up first into water, salts, and fat, thus becoming completely transformed. This is a matter of vital importance. Prevent the pus from forming if you can, but, when formed, properly remove it. The knife is not always necessary, however, for this purpose. Surgical treatment has here trenched in some instances upon the domain of medicine. The advantage of this method over the knife can be actually seen in abscesses of the lymphatics of the neck, occurring in young patients who have been living on such food as jam, jellies, fresh bread, cake, fruit, and ice cream.

I have also used this method on patients with pelvic abscess and high fever due to septic absorption. They were so emaciated that one could almost encircle the calf of the leg with the thumb and finger; they suffered agonizing pains, and probably could not have stood the shock of an abdominal operation. Their recovery under this treatment was, however, rapid and complete.

The ingestion of an excess of carbohydrate food I believe tends to the development of bacteria in the digestive tract, and wherever pus is present.

In these cases of chronic sepsis there is a great strain upon the kidneys, and hence the water taken is of great benefit. In cases of pyosalpinx with operative interference alone the results are not at all so gratifying as where this method of treatment is employed. When a writer says, in speaking of salpingitis, "If there is suppuration there should be no question as to the propriety of an operation," I disagree with him decidedly. This same writer then goes on to show the advantage of operating in *all* cases by saying: "To ascertain the real benefits of operation for this disease, one must not decide until quite a long period of time has elapsed." No one can say that abdominal sec-

tion is a perfectly safe operation, as it is common for patients to die under it; nor does it always remove the disease along with the tubes and ovaries.

If a patient dies from an operation where proper medical treatment would have readily cured her, what does the white sheet cover? Nothing more or less than a case of scientific murder; but then ignorance excuses a great deal. While we should be conservative, we must not be cowardly.

In the cases of ulcerating appendicitis and other conditions which we find impossible to resolve, and which demand operation, temporizing often leads to a fatal issue. When procrastination is indulged in without reason after proper treatment has failed, the delay probably kills even more in this department than elsewhere. This is notably seen in cases of hernia, where stercoraceous vomiting and collapse are sometimes present before an operation is advised.

NO. 776 MADISON AVENUE.

THE

CLINICAL STUDY OF THE BLOOD IN ANÆMIA.*

By THOMAS S. SOUTHWORTH, M.D.,

PATHOLOGIST TO THE NURSERY AND CHILD'S HOSPITAL;
ASSISTANT, DEPARTMENT OF MEDICINE, VANDERBILT CLINIC;
INSTRUCTOR, DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

Blood has been well described as a tissue possessing cells and a fluid stroma. With the peculiar characteristics of the latter, its alkalinity or specific gravity, subjects carefully investigated of late, I shall not attempt to deal this evening. The red blood-cell has long been studied assiduously from the standpoints of origin, normal and pathological existence, procreation, and ultimate destiny. In embryonal life the red cells are formed from the endothelium of the blood-vessels and from other red cells containing nuclei. During the latter part of this period the liver and the spleen are endowed with hæmatopoietic functions, as is also the marrow, and nucleated red cells circulate freely in the blood. At birth, however, or shortly thereafter, the spleen and liver relinquish this function and the nucleated red cells are retired from the circulation and exist only in the vaults of the marrow. From this time on nearly all agree that in health the red blood-cells are formed exclusively in the marrow, but there is more diversity of opinion as to the mode of their formation. They probably have their origin from the nucleated red cells there present, either by the budding of their protoplasm (Malassez), or by division of the nucleus and cell with subsequent extrusion of the nucleus (Rindfleisch), or by division, with subsequent disappearance of the nucleus (Foà). These theories are the more plausible in that they are in accord with the fetal methods of formation, concerning which there is a very considerable unanimity of opinion. Denys's proposition that they are formed by budding from the endothelial wall of the venous capillaries of the marrow, and Hayem's dic-

tum that they are derived from the hæmatoblasts, may also be mentioned.

In pathological processes the red cells suffer deterioration in respect to numbers, color, shape, size, resistance to outside influences, capability of forming rouleaux, and the presence of nuclei. These changes, with the exception of nucleation, can be detected in specimens of fresh blood, and furnish invaluable assistance in the detection and diagnosis of disease.

The methods of counting the red cells and of estimating the percentage of hæmoglobin are well known. In short, the use of the hæmocytometer and hæmoglobinometer requires no comment. The chief principle exemplified by those diseases which primarily affect the red cell is contained in the following brief and mathematical proposition: In chlorosis the percentage of red cells is greater than the percentage of hæmoglobin; in simple anæmia the percentage of red cells equals the percentage of hæmoglobin; in pernicious anæmia the percentage of red cells is less than the percentage of hæmoglobin. This, like many other rules, must be allowed its exceptions and must not be accepted too literally, as evidenced by the fact that the exhibition of hæmatinics in any case of anæmia is followed first by an increase in the number of red cells and more tardily by increase in hæmoglobin.

Change in shape is a more intricate matter, as it affects both the circumference and thickness of the cells. Poikilocytosis is the term generally used to denote these changes when they are present to a decided degree and the cells are tailed or kite-shaped or present other marked irregularities. This term and condition are not confined, as was once thought, to pernicious anæmia, but poikilocytosis may be also present in any advanced anæmic condition, whether there be defective formation or increased destruction of the red cells. Schistocytosis is a comparatively new word coined to denote the existence of those poikilocytes which appear to be parts broken off from large cells or the portions of disintegrated cells. Slight changes are evidenced in the loss of the normal clear circular outline or a tendency among all the corpuscles to assume an oval form. Shape is further affected by the presence or absence of the biconcavity of the cell, and cells are found especially in chlorosis where no concavity exists; in fact, the cells are biconvex and in consequence are thicker, contain more hæmoglobin, and both appear and stain deeper in color. Shape as dependent upon decreased resistance will be treated of later.

In normal blood the red cells appear under the microscope to have almost the same size, and when lying side by side present almost the regularity of tessellated pavement. As soon as any deterioration, however, occurs in the condition of the blood the size varies and soon red cells may be divided into microcytes or small cells, normocytes or average cells, and megalocytes or large cells. In chronic secondary conditions microcytes exist in large numbers and the cells average small. In pernicious anæmia, however, the predominance of very large cells or megalocytes becomes one of the diagnostic features. In all moderate conditions of anæmia very considerable variations in size become notice-

* Read before the Section in General Medicine of the New York Academy of Medicine, April 18, 1893.

able and may be the only conspicuous change on inspection. This condition precedes as well as is coexistent with poikilocytosis and is presumably ascribable to poor workmanship in the hæmatopoietic factories, due to the ill-nourished condition of the workmen, an inadequate supply of raw material, and perhaps also to the poverty of the medium in which the product later circulates. The red cell in robust health is not only well formed, but it possesses greater resistance to outside influences. Changes so produced are most familiarly evidenced in the crenation of the corpuscle upon the contact of air, beginning near the edge of the cover glass and extending throughout the specimen. It also includes the swelling and distortion of the cells when exposed to the action of various chemicals in solution. One of the first things which one notices in examining a series of slides from different cases is that crenation takes place in some much earlier than in others. Investigations in this direction have as yet furnished us with no very practical data. In general, it may be said that decreased resistance keeps pace with the advance of the anæmic condition and is presumably dependent upon defective formation or imperfect nutrition of the cells. Cells have their own life period and are doubtless also more vulnerable at certain stages of their career than at others. The chemical constituents of the plasma in various pathological conditions have recently furnished a field for active investigation, especially as before mentioned with reference to the alkalinity and specific gravity; but as the methods employed invade the intricate field of analytical chemistry and present no diagnostic results which can be demonstrated to the eye in microscopical examination, we must omit their consideration. One point of interest with reference to the plasma still remains to be mentioned. While the serum of normal blood has no effect upon the hæmoglobin in the red cells, in pernicious anæmia it is found to readily abstract it from the corpuscle and to be tinged by it, on account of the lighter union between the hæmoglobin and the stroma of the cell. This brings us naturally to the three theories advanced to account for the larger percentage of hæmoglobin than of red cells in this disease, and these we are now in a position to consider as follows:

1. That the individual red cells being larger than the normal average, they contain more hæmoglobin than the same number of cells of average size.
2. That the plasma contains additional hæmoglobin in solution from cells which have been destroyed.
3. That, owing to the lighter union, all and not a part of the hæmoglobin is dissolved out of the cells, and therefore higher results are obtained.

The capability of forming rouleaux seems to be dependent upon several of the foregoing conditions, especially those of form, size, and resistance; for it is at once evident that coins of different denominations, especially if mutilated, would form poor rouleaux. In ordinary chlorosis their formation is good, in moderate anæmia fair, in advanced anæmia poor, and in pernicious anæmia it is lost.

Nucleation is not a characteristic of the normal red corpuscle in extra-uterine life, but its presence is always a sign of a desperate struggle on the part of the hæmato-

poietic organs. The nucleated red cells have been compared to army reserves which are only brought into action when the forces already in the field prove incapable of sustaining a winning fight. Any adult anæmia may show them when it has advanced to a sufficient degree, although they may be rare and require the examination of several slides before one is discovered. But, to continue the simile used above, just as in a sudden attack, when the forces are surprised and the loss of life great, the reserves are more quickly pushed to the front, so in the anæmia following hæmorrhage and in that due to poisoning by arsenic, phosphorus, etc., the nucleated red cells appear quickly and are most numerous. This has been considered a reversion to a fetal type of blood formation, and the idea is somewhat substantiated by the fact that in the anæmias of children, in which such a reversion would be more natural, the nucleated red cell is found earlier and upon less provocation.

Three forms of nucleated red cells are described—microblasts, normoblasts, and megaloblasts or giantoblasts. These will readily be seen to correspond to the three types of non-nucleated cells—microcytes, normocytes, and megalocytes—above described. Of these, the microblasts are of exceedingly rare occurrence. The normoblast is the common form whose occurrence we have just described. The megaloblast, however, deserves special mention, as it is almost pathognomonic of pernicious anæmia. It corresponds to the megalocytes which are so numerous in this disease, and shows, when stained, a larger nucleus than the normoblast. It has not, however, the reproductive power of the latter, for when the nucleus leaves the cell it dies and does not continue to form other red cells; hence their presence does not assist in staying the advancing anæmia and hetokens, wherever they appear, the approaching exhaustion of the blood-forming resources. Nucleated red cells which show the nucleus in the process of division are often found in the late stages of leukemia in large numbers, and more rarely in other conditions. Nucleation can not be made out in fresh blood, and for its recognition both nuclei and protoplasm must be stained.

According to von Limbeck, clinical nomenclature is accustomed to distinguish two classes of anæmia—primary and secondary—those cases being classed as primary where the symptoms of anæmia monopolize the clinical picture, while in secondary anæmia the anæmic symptoms are thrown into the background by those of the organic disease, upon which it depends. Although this division line can not be strictly drawn and we often meet cases in which we are in doubt as to which class they shall be relegated, still, for clinical purposes, such a classification is indispensable. Under the clinical conception of primary anæmia we are accustomed to group—

1. Simple primary anæmia.
2. Progressive pernicious anæmia.
3. Chlorosis.

Each of these divisions presents its own symptomatology, partly dependent upon the condition of the blood and partly upon the disturbances in the various organs. It is the condition of the blood with which we have to deal.

Simple primary anæmia with its wide range of ætiological factors presents both acute and chronic stages. In the acute stage the reduction of red cells and hæmoglobin go side by side as the destruction of a red corpuscle removes a corresponding amount of hæmoglobin from the circulation. Following this there may be a slight increase in the white cells, but these quickly return to the normal and are not a characteristic feature. As the process advances, marked poikilocytosis occurs and nucleated red cells appear. The blood plaques also may be increased.

The general practitioner is still somewhat in the dark as to what cases shall be included under pernicious anæmia, cases of advanced anæmia being constantly so classed which, although progressive and fatal, are manifestly of a secondary and not of an essentially primary nature. The sanguinologist, however, claims that this diagnosis should be limited to cases where the affection is primary or where the coexistent condition can not be held accountable for so advanced an anæmia. He also demands that the condition of the blood should conform to the following standard: In pernicious anæmia the percentage of hæmoglobin, although very low, is higher than that of the red cells. The power of forming rouleaux is lost. There is an astonishing reduction in the number of red corpuscles to below a million, or even below five hundred thousand. Individual red cells may be much distorted, constituting marked poikilocytosis with irregular distribution of the coloring matter in the cell. Degeneration forms and fragments of cells, known as schistocytes, are seen. A large number, however, of the red cells are very large and are known as megalocytes. Nucleated red cells, both of average and very large size (normoblasts and megaloblasts), appear. The number of leucocytes is not increased, but a reduction in their numbers keeps pace with that of the red elements.

Chlorosis has its characteristic clinical picture and a characteristic blood condition, in which latter the red cells remaining on the whole of good size, shape, and especially numbers, the hæmoglobin shows the chief change and is considerably reduced. Thus chlorosis affects chiefly the hæmoglobin, while anæmia affects the red cells. There are undoubtedly some cases of advanced chlorosis with decreased numbers of red cells and poikilocytosis, but these cases are relatively rare and are looked upon as a combination of anæmia with chlorosis. Nucleated red cells only appear in the severer cases. Leucocytosis is not found in pure chlorosis.

Another type of anæmia remains to be mentioned for the sake of completeness. I refer to secondary anæmia. In this, the process having settled down upon a continued morbid basis, the hæmoglobin and red cells are decreased equally, the bulk of the red cells are microcytes, and the mass of the red cells average small. There is leucocytosis, and the large mononuclear leucocytes are increased in numbers. No nucleated red cells are present, spasmodic efforts at regeneration having long since been abandoned. Such a condition accompanies syphilis, hæmorrhage, cancer, tuberculosis. Acute heart cases often give the appearance of anæmia where none exists, due to the bad local tonus of the vessels.

Too often cases are classed as anæmia without inquiry as to an existing cause, the anæmia is treated without success, and the underlying factor disregarded. Anæmia should always lead us to look for incipient phthisis, for cardiac and renal disease, for malignant growths, for causes of disturbed nutrition, for sources of hæmorrhage. Too often valuable time is lost through this omission.

With reference to the treatment of simple anæmia we should not forget the probable existence of an underlying cause or the fact that anæmia is not a local but a systemic disease, that cause and effect are here retro-active, that while malnutrition may cause anæmia, anæmia certainly increases the malnutrition. It is due to these facts that hygiene, dietetics, and hydrotherapy are often as useful as the administration of hæmatinics. It is the combined attack which wins. The anæmic dispensary patient often improves under treatment; the same patient in the hospital almost invariably does so, because of environment, diet, and rest in addition to medicinal treatment.

The use of iron to restore the hæmoglobin is accepted. The indications for arsenic are not as well understood. I have seen the blood of patients who had been receiving increasing doses of arsenic remain in the sealed chamber or subjected to the three per cent. salt solution of the usual Thoma-Zeiss hæmocytometer for hours without crenation. As the result of repeated examinations of the blood of such patients, I believe that arsenic exerts its chief action upon the blood-forming organs, where by their product the red blood-cell is rendered of better quality and of greater resistance.

19 WEST FORTY-SIXTH STREET.

A STUDY OF THE USE OF BORAX IN EPILEPSY, WITH THE REPORT OF A CASE.

By EDWARD A. WELCH, B.S., M.D.,
SUTTON, MASS.

On May 7, 1892, I was called to see Miss L. P., aged thirty-eight years. Found her subject to nocturnal epilepsy (epilepsia major), which had troubled her from early childhood and for which she had been under almost constant drug treatment with no permanent relief. The disorder was said to have originated after some slight head injury received [this causation must be a matter of doubt], and the attacks had occurred at irregular intervals since, some of the time two, three, and four times a night, with occasional remissions under bromide and other treatment. The mental faculties, at the start normal, had become much impaired the woman being childlike in actions and apparently in thought, though capable of doing ordinary housework under supervision. She was gloomy, irritable, and melancholy.

From the history given me, I judge that at an early stage in the disease treatment by bromides, potassium iodide, etc., had been tried by the attending physicians. Often there had seemed to be temporary improvement for a few weeks, but soon (possibly from acquired tolerance of the drug used) the patient would relapse to her former state. At last the family adopted the prescription of a well-known local practitioner, and for some years had been dosing the woman with a mixture

of potassium bromide and potassium iodide—satisfied if the epileptic attacks did not occur more often than once each night. As a result, symptoms of bromidism—acne, fetid breath, coated tongue, heart's action rather slow and feeble, muscular movements tremulous—were present. The digestive and excretory functions were much disturbed.

It was, in truth, for relief of the disordered digestion that I was called to the case, as almost anorexia had ensued, with concomitant alarming weakness; the epileptic condition was regarded as past all mending.

Treatment.—Bromide mixture stopped at once. Liquid diet for two weeks, ingestion of plenty of hot water every morning, preliminary cleaning out of effete matter by a quart of a grain of calomel every hour for six doses, *pepsin*, *nux vomica*, and *bismuth*, with occasionally the addition of powdered charcoal in appropriate doses after each meal,* soon improved the digestion greatly. I then determined to endeavor to at least alleviate the epileptic condition, which had manifested itself by two and three attacks each night for some weeks before and also during the treatment detailed above.

Both reading and a little previous experience led to hopes that the use of borax might be beneficial. Accordingly I administered at 12 noon and at 4 and 8 P. M. powders of sodium baborate, ten grains in a third of a glass of water. This makes rather a nauseous drink, but was not objected to by the patient, whose taste was quite effectually blunted by the long course of bromide. Later on I found that the addition of some aromatic, such as ginger or cinnamon, improved the taste. No other drug was given. All easily digested food was allowed. No improvement was noted for nine days, and I was strongly tempted to make some addition to the borax, but on the tenth night only a single "fit" was reported. The borax had caused the bowels, ordinarily constipated, to become fairly regular, with one or two soft movements daily. On the twentieth day she was reported to have had "but four attacks during the last week." A temporary loss of appetite at this time was mended by a week's use of half an ounce of the compound syrup of the hypophosphites (N. F.) before each meal.

From June 1st to June 7th there were no attacks. "Better in every way than she has been for three years back," said the parents. On July 9, 1892, my notes say "improvement as regards epileptic attacks still continues; has very few, and these seem less severe and of less length than before. Appetite good."

The noon powder was henceforth omitted. At this time I began to dispense borax purchased at a grocery store. Ten days later I found that the patient had been affected for a week past with choreic movements of the muscles, the spasmodic contractions being often so violent that she would fall helplessly to the floor. I stopped using the commercial borax and gave instead the chemically pure article. Gave a thirtieth of a grain of arsenic bromide three times a day, and the condition gradually mended and has not shown itself since. The later history of this patient is the uneventful one of continued improvement. The borax is given now but once a day, ten grains at 4 P. M.

Epileptic seizures occur but once or twice a month, and these more often at the menstrual epoch. An attack of epidemic influenza in April, 1893, was accompanied by a number of convulsions, but with the subsidence of the acute disease the attacks again ceased.

The result of borax treatment has been so far most gratifying, the patient being better than at any time since the disease became fully established. The mental state shows little im-

provement; nor can it be expected. There seems good ground for hope that longer use of the drug will result in still greater freedom from the nocturnal convulsions.

The ordinary reference books at command of the practicing physician give very brief and meager reports on the use of sodium borate; therefore I here present the results of careful study of the published literature of the drug. Sodium baborate, or borax, has been tried by different observers as a remedy in epilepsy for a number of years. As in the case of all newly applied drugs, a period of enthusiastic use was followed by a period of distrust, and at least one of our leading American authorities casts aside the drug as of no account in epilepsy. Study of reported cases, however, seems to show that, while the drug has its limitations, while its use can never be as generally successful as the bromide treatment, in certain cases great benefit may be derived from it. Reports of little or no benefit come chiefly when it has been used in cases where the attacks occur mostly or wholly by day. The most successful cases are those in which the attacks are nocturnal. It is, of course, a truism that successes are most likely to be published and failures are passed by in silence; but there is on record enough in the way of good results to warrant a careful trial of borax in epilepsy whenever the attacks are chiefly nocturnal, and we may do so with good hope of obtaining relief. In cases where bromide or other drugs have not produced good results we may also try the drug for day attacks, for a few well-authenticated cases of improvement are on record. The bromides must remain as the mainstay of treatment; but in many cases, even when by such treatment we get good results, unless we are fortunate enough to get a speedy cure, there are very apt to follow, sooner or later, certain ill results and disadvantages. Gradual increase in dosage where palliation only is hoped for is the rule, causing disagreeable symptoms which in some cases may make the remedy a source of more annoyance than the convulsions. Not only may "bromism" with its attendant evils follow too thorough saturation of the system with the drug, but when doses within the physiological limit are taken we may get disturbance and loss of appetite with more or less loss of flesh and strength, and often dullness of intellect and mental apathy so marked as at first sight to suggest permanent mental impairment.

If, then, a drug much less noxious, such as borax, can in certain cases be effectively substituted, it is well to use it. It is certainly worth the trial.

Dr. C. F. Folsom (*Boston Medical and Surgical Journal*, 1886) quotes details of two cases in which careful treatment by bromides and other drugs (in the hands of accomplished practitioners, who would be likely to exercise care as regards diet and hygiene) had been of little use, and the bromide not well borne. The administration of borax caused great improvement, the fits being reduced to two in a year and two in eighteen months, respectively. One patient was rescued from a state of isolated invalidism, and was able to enjoy social pleasures. Gowers, in his textbook, recommends borax as useful in some cases where bromide has no influence.

Russel and Taylor (*Lancet*, 1890) give a tabular review

* *B* Pepsini puri, gr. $\frac{1}{2}$; ext. nuc. vom., gr. $\frac{1}{4}$; *bismuth*. subnit., gr. iij in each dose.

of twenty cases treated by them in hospital. In all the bromide treatment had failed. They used the drug in rather larger doses than we are accustomed to—giving forty to sixty grains daily in many instances. Of the twenty patients, five had no fits after beginning treatment, nine were greatly improved, four were slightly improved, and in two no change was noted. Treatment was continued in the more successful cases four to six months, while in some of the cases, where little improvement was made, the borax was stopped in three to six weeks.

Dr. H. S. Hill's case (*Medical News*, 1889) had a duration of eight years; the patient, sixteen years old, had one or two attacks each week. Was put upon ten grains of borax three times a day, and at the time of the report much improvement had been noted for three years, the fits occurring not more than once or twice a month.

Borax is most useful, according to J. D. Munson, in those epileptics with low arterial tension but strong heart action, as the drug seems to constrict the peripheral blood-vessels in a remarkable degree, and so is in a measure antidotal to the condition of cerebral anaemia, which undoubtedly plays a part in the causation of the paroxysms.

As regards dosage, ten grains three times a day has been found sufficient in most cases, although the amount can be largely increased if necessary without evil result. Dr. G. M. Hammond states that if one hundred and twenty grains in the twenty-four hours is not sufficient to control the paroxysms, larger doses will be useless. Digestion will be less interfered with if it is given as far away from meal times as possible. Great care will, of course, be paid to the digestive functions of the patient, and it is to be remembered that overdosing may produce interference with general nutrition. Tonics should be added when indicated. As nausea and vomiting sometimes result from the disagreeable taste of the drug, it may be given in strong coffee, licorice mixture, or combined with aromatics. I have lately tried a compressed tablet containing five grains of borax and half a grain of ginger, which has appeared to work well, no bad result having been yet noticed.

During the administration of the drug certain ill effects may be produced, and should be watched for and guarded against. The first doses sometimes cause diarrhoea, which usually ceases in a few days. Should it continue, or be accompanied with vomiting, appropriate doses (five to ten grains) of bismuth salicylate will be found an effectual corrective.

Folsom noticed a scaly eruption, which disappeared when arsenic was administered. One patient was troubled with vomiting at the commencement of the treatment, but this ceased when aromatics were combined with the borax.

Skin eruptions not infrequently occur, both papular and scarlatinous. A case of the latter ran a course similar to the drug eruptions produced by quinine sulphate, which I reported in the *Medical News*, September, 1891. This eruption is at times followed by desquamation. Féré quotes two cases where an eczematous eruption was produced by thirty grains three times daily, and which faded only on discontinuance of the drug. He considered these ordinary cases of eczema provoked by borax in persons who were

predisposed to that disease. Russel and Taylor observed in one patient, a woman aged twenty-five years, an attack of dry pleurisy. "At no time was there evidence of effusion. The patient had never had a similar attack before, and, as no history could be obtained of any of the usual causes of pleurisy, it might be suggested that the affection of this serous membrane was similar to that which we had seen in skin and mucous membranes, and depended on the biborate of soda." These observers also noticed that several patients complained of sore lips while taking the borax.

Munson reports a case where suppuration of the middle ear was always produced by use of the biborate.

In the case reported in this article the sudden onset of choreic movements was coincident with the use of commercial borax, which may have been impure. To secure best results, I advise the use of sodium biborate of known purity. Dr. H. W. Williams, of Boston, who has made extensive use of borax for many years in his ophthalmic practice, says that, unless care is used, one is liable to get adulterated or impure samples, and he advises buying the crystals rather than the powdered borax. With the exception noted above, I have used the sodium biborate, crystalline, prismatic, chemically pure, obtained through Merck; for, doubtless, lack of result in drug treatment is often due to the use of drugs not up to standard purity or strength.

"HYGIENIC CLOTHING."

By R. C. RUTHERFORD.

In the *New York Medical Journal* of April 23, 1892, there is an article on this subject, by Frank H. Daniels, A. M., M. D., who begins by telling us that "at the present day scientific clothing enters so largely into the modern economy that it is important for us medical men to look back occasionally and review the progress which has been made in this department."

Now, in view of the fact that there are a great many modern economies, it is not easy to see what the doctor means by "the modern economy." The only kind of "modern economy" to which the doctor's language seems applicable is that which is defined to be "the management of a family." If Dr. Daniels is in possession of statistics which warrant him in saying that scientific clothing enters largely into the management of the family, as a rule, he ought by all means to give the world the benefit of them. The most discouraging thing about this question to those who, like Dr. Daniels, appreciate the importance of hygienic clothing, is the difficulty of getting people to consider it from a scientific standpoint at all.

That the doctrine of hygienic clothing is beginning to assert itself in the professional literature of the day (and this is probably what the doctor means) is one of the most gratifying signs of the times. And that this literature is beginning to tell upon the reading public is the great hope of the reformer.

The next queer thing in the doctor's paper is the manner in which he looks back to "review the progress which has been made in this department"—of hygienic

science, one may suppose. He leaps over a period of one hundred years to quote some passages from Count Rumford demonstrating the superiority of wool over *all other materials* of clothing for the human body; and then he bounds back again to light on the "Jaros material," a novelty of the day (consisting chiefly of cotton), as the "practical accomplishment of scientific theories."

The logical connection of this conclusion at one end of the century to the major proposition at the other end of it will be more likely to be appreciated if we supply a few missing links—although, unfortunately for the doctor's notion of "progress," the links themselves are mainly at the two extremes.

Let us see! The doctor says that "an ideal clothing is one which does not interfere with the functional activity of the skin, while *it* at the same time protects *it* against sudden changes of temperature." (The *Italics* are mine.)

Without stopping to particularize the defects of such a definition, I may remark that the doctor himself tells us that as "raw silk can not be used"—for clothing, presumably—"wool stands at the head of our list." And he also quotes the *Medical Record* of January 15, 1887, in confirmation, thus: "There is no doubt that wool stands at the head of the materials out of which clothing is made." And then the doctor adds: "It will be seen from what has been already said that wool answers each one of the requirements of a perfect clothing material in the highest degree."

The reader of the doctor's article will perceive that the properties which put wool at the head of the list as a clothing material supply, by implication, the reasons for rejecting linen and cotton as a clothing material for wear "next the skin."

Now we are prepared to formulate the doctor's logic: The experiments of Count Rumford, Parkes, and Pettenkofer, the testimony of the *Medical Record*, and Dr. Daniels himself establish the fact that "wool answers each one of the requirements of a perfect clothing material in the highest degree"; therefore the Jaros clothing material, consisting of cotton (or silk) and wool, is "the most perfect clothing fabric made." And one may suppose that this last clause is what the doctor means when he says that the Jaros material is "the practical accomplishment of scientific theories." If not that, what? Any one is at liberty to guess.

Taking this as a fair sample of the doctor's method as a logician, I pass to notice some examples of his style as a scientist, with the greater warrant since it is in that capacity, and not as a "tailor," that the doctor appeals to his readers.

He says: "The outer clothing may indeed adorn; the inner must be made on scientific principles, and the latter is of the greatest importance."

From the doctor's exposition of the functions of the skin, it is evident that he wishes to impress upon us the idea of its importance chiefly as a system of drainage and a regulator of animal temperature. And it is on this ground that he insists that the "inner [clothing] must be made on scientific principles"; but, as "the outer

clothing may indeed adorn," it may, inferentially, be made regardless of scientific principles.

Now let me ask the doctor how he would like to have the plumbing of his residence constructed on such a principle? Would he be content to have the drainage to the outer walls of his habitation constructed without reference to the sewerage beyond? Would a sewer main that obstructed the efflux of the refuse and turned it back to his own cellarage and up into his waste pipes, closets, and wash-bowls accord with his idea of a perfect sanitary system of plumbing and sewerage? Or would he admit that the sewerage branch of the sanitation should be made upon scientific principles, as well as the house-drainage portion? And if he would, would he not as readily admit that the outer clothing should be of such material, and so constructed, as to present the least obstruction to the dissipation of the excretions of the skin taken up by the garments next to it?

The doctor's definition of an "ideal clothing" declares that it shall "not interfere with the functional activity of the skin"; but it does not seem to have occurred to him that any portion of the clothing except the "inner" is capable of such interference. Can a physician that is ignorant of this important truth be said to "understand thoroughly what is required of good clothing?"

Let me suggest the following as a substitute for the doctor's definition: A scientific clothing for the human body is one which, in material and construction, should co-operate with the skin as an excretory, an absorbent, a breathing, a digesting, and heat-regulating organ.

The doctor next informs his medical brethren that "the normal skin is an excretory as well as a secretory organ"—as if the distinction were a matter of some importance; and yet he nowhere explains the difference between its secretory and excretory functions, presuming, probably, in that respect, upon the intelligence of his professional hearers. Or possibly it occurred to him that its secretory and its excretory action are identical—that is, its secretions are its excretions. Or, if the doctor means that its secretions are the contents of the perspiratory glands and its excretions the excreted perspiration, why does he proceed to inform us that, "if the skin is not acting normally, its excretions are taken care of by the other excretory organs—viz., lungs, kidneys, and bowels"? Surely the lungs, kidneys, and bowels are not going to bother themselves with excretions that have already been excreted, and they can hardly be called excretions until they have been excreted. Is the doctor's eye so single to the glories of the "Jaros underwear" that it is insensible to so glaring an absurdity? The doctor very properly dwells upon this excretory action of the skin in its relation to the health and well-being of the individual, and by his explanations imparts somewhat of a scientific tone and purpose to his communication. This is followed by quotations (already referred to) from several high authorities—all to the point of the peculiar fitness in all respects of wool as the material for a clothing to insure the normal action of the skin's various functions. But suddenly there comes a suggestion that something is lacking. Close upon the heels of his statement that "wool

answers each one of the requirements of a perfect clothing material in the highest degree," he asserts that "it only remains for us to determine how wool shall be used so as to take the greatest advantage of its properties." If the doctor says what he means, he is quite right in averring that it remains to be determined how wool can take advantage of its own properties, and why it should want to take advantage of them is quite as undetermined. Probably the doctor wanted to say that it remains for us to determine how wool can be used in order to make its properties most available to us. Manifestly there is no need to take advantage of them. But let us go on with the doctor:

"Until recently," he says, "the only woollen fabrics we have been acquainted with practically have been flannel, where [*sic*] the wool is first spun and then woven more or less lightly into a fabric. By this means the value of all the properties which make wool pre-eminent as a clothing fabric is diminished; and laboratory experiments made with wool as it comes from the sheep do not agree with those made on flannel—*i. e.*, spun and woven wool."

Dr. Daniels is quite right in saying that, until recently, the only woollen fabric we have had any knowledge of has been flannel. Yes, *flannel*—the coarse, heavy, rough, old-time flannel of our grandmothers! It was of this kind of flannel that Count Rumford wrote, over a hundred years ago (not recently, observe):

"I have worn it in the hottest climate and in all seasons of the year, and never found the least inconvenience from it."

This is Rumford, as quoted by the doctor. But this that follows is some of the Rumford that the doctor did not quote. Probably the doctor overlooked it, though it was next-door neighbor to the passage cited by him:

"The perspiration of the human body, being absorbed by a thick covering of flannel, is immediately distributed through the whole thickness of the substance, and by that means exposed to a very large surface to be carried off by the atmosphere; and the loss of this watery vapor, which the flannel sustains on the one side by evaporation, being immediately restored from the other, in consequence of the strong attraction between the flannel and this vapor, the pores of the skin are disencumbered, and they are continually surrounded by a dry, warm, and salubrious atmosphere."

"I am astonished that the custom of wearing flannel next the skin should not have prevailed more universally. I am confident it would have prevented a multitude of diseases; and I know of no greater luxury than the comfortable sensation which arises from wearing it, especially after one is a little accustomed to it."

The fact is that these two passages are the meat to the sandwich as prepared for us by Count Rumford. For some reason, in "passing it round," Dr. Daniels has permitted the meat to slip out, and served us with the pastry only. Was it because the doctor perceived that the meat was not amenable to the digestive capacities of a Jaros-wool-lined-cotton-back stomach?

The observations and experiments that demonstrated the truth that "wool answers each one of the requirements

of a perfect clothing" related to these very old-time flannels, vastly inferior to the recent products of our present manufacturers. It was those old-time flannels that "greatly promoted insensible perspiration"; it was those old-time flannels that disencumbered the pores of the skin" and kept them "constantly surrounded by a dry, warm, and salubrious atmosphere." It was those old-time flannels the wearing of which, Count Rumford believed, "would prevent a multitude of diseases." And it is this same old-time flannel which, according to Dr. Daniels, by reason of its "longitudinally" laid fibers, diminishes "the value of all the properties which make wool pre-eminent as a clothing fabric."

Hear him again:

"In order to preserve the absorptive property of wool in the highest degree, the fibers must be arranged with their points against the skin, and not longitudinally, as in a woven fabric."

At first it is the absorptive property that is to be thus preserved; and next we are told that the arrangement preserves "unimpaired all the properties which make wool valuable as a clothing fabric." And then he *recapitulates* the properties in *this way* (the Italics are mine): "It should be hygroscopic, porous, and so loosely woven as to include more or less air in its meshes."

Now, as two of the doctor's *properties*—namely, "should be porous," and "should be loosely woven"—are resolvable into one, "porosity," it is evident that his "all the properties" are only two—hygroscopicity and porosity.

As the "framework" of the Jaros garment is a woven fabric, its meshes—porosity—being formed by fibers "longitudinally" arranged, the property of hygroscopicity, "the absorptive property," is, by the doctor's own statement, diminished—seriously impaired; even the animal temperature being no longer regulated by the fabric, because, according to the doctor, "our bodies lose just as much heat as the moisture in the clothing is capable of absorbing." The doctor should have said "capable of absorbing and dispersing by evaporation."

It is in vain that the doctor tells us:

"The arrangement of the wool is such that, by capillary attraction, perspiration is absorbed and carried to the silk or cotton back, whence it is evaporated into the surrounding atmosphere"; since the silk or cotton back, having its fibers longitudinally arranged, has but a "diminished" absorptive property of taking up and conveying the perspiration to the atmosphere from the hygroscopic wool through to the unhygroscopic silk or cotton.

We have the doctor's word for it that "the material which will retain the least moisture is the best"; and that "woolen fiber is found to answer this purpose more nearly than any other." Therefore, according to the doctor's logic, a little wool with a thick "cotton back" "may be said to be the most perfect clothing fabric made," because it is "unspun wool caught into the mesh [*meshes*] of a loosely knitted cotton back in such a manner as to preserve unimpaired all the properties which make wool valuable as a clothing fabric."

And the "value" of all these properties—that is, all

two of them—"is diminished when the fibers are arranged longitudinally, as in a woven fabric."

It is obvious, from the doctor's own enumeration, that "all the properties which make wool valuable," etc., are hygroscopicity and porosity, and both of these are impaired by the longitudinal arrangement of the fibers, the very arrangement that predominates in the Jaros fabric, and that, too, with a cotton fiber in all respects inferior to wool as a clothing material.

Now, for what conceivable purpose has Dr. Daniels involved himself in this ridiculous snarl of contradictions and absurdities?

It is only recently that the doctor has "had his attention called to it" and tested it; nevertheless, he "must confess that nothing has given him such personal satisfaction and comfort."

As the doctor's hygroscopicity of wool has been seriously impaired by his longitudinality of fiber in the fabric, let us see if we can not restore its integrity by a more consistent process. To recover this property, so essential to the hygienic value of wool, we may have recourse to the doctor's "highly porous Jaros material" and von Ziemssen's "loose texture," in spite of the longitudinal arrangement of their fibers, and then we shall have as a list of "all the properties" (but not according to Dr. Daniels):

1. Hygroscopicity, or "attraction of wool for water in its elastic state—vapor" or "next,
2. Repulsion for water in its liquid state; then,
3. Non-conductivity, relative to heat and electricity, a warmth-preserving property; next,
4. Attraction for atmospheric air, another important factor in the preservation of warmth; next,
5. Repulsion for filth and offensive odors—a self-cleansing property of the animal fiber.

And thus we have five properties which combine to make wool meet all the "requirements of a perfect clothing material in the highest degree"—"which make wool pre-eminent as a clothing fabric" (observe, as a clothing fabric), and all of which are seriously diminished (according to Dr. Daniels) when the fibers of the clothing fabric touch the skin "longitudinally."

But, as we have seen, it is chiefly the absorptive property of wool, its capacity to take up and disperse the moisture of perspiration, that especially suffers from the doctor's longitudinality of contact. So says the doctor; but, unfortunately for the doctor's pretty story, directly the reverse of this is the fact. Any common horse-jockey or stableman could have told him better. When the warmth of the body of perspiring animals is to be especially preserved against a low temperature, the hair, fur, or feathers, as the case may be, automatically adjust themselves to a perpendicular to the skin, thus increasing the air spaces between the fibers and the quantity of air retained by them—a positive obstruction to both absorption and radiation. But when the animal heat is raised to the point of perspiration (sensible perspiration), the hair is laid flat, parallel to the skin, expelling proportionally the interfibril air, and increasing the conditions favorable to capillary attraction and a copious outpouring of perspira-

tion. Probably Dr. Daniels himself, if he is anything of a whip, has more than once boasted that he could drive his mare for miles and "not lay a hair on her." When the cold season approaches, the hairs, the coat of the animal, multiply and lengthen, and stand out straight from the hide; and it is a bad sign for the animal, as denoting a suppressed perspiration, and fever, when the hair so stands out in warm weather. Capillary attraction is the most effective, and perspiration most abundant, when the hairs are approximated and laid close to the skin, and least so when raised endwise to it, for cold and terror both drive the blood from the skin, blanch the cheek, and make "each particular hair to stand on end, like quills on the fretful porcupine."

When the doctor tells us that "the arrangement of the wool is such that, by capillary attraction, perspiration is absorbed," etc., does he not forget the distinction between hygroscopic and capillary attraction? He would have spared himself some confusion if he had kept well in mind the fact that capillary attraction takes effect upon liquids only, and hygroscopic attraction upon vapors only.

Again, if Dr. Daniels will make the experiment, he will find that it is simply impossible to maintain the woolen fibers of a Jaros shirt in the position of perpendicularity to the skin. The pressure of the slightest contact is sufficient to lay them all flat-long. The fibers that were coarse and stiff enough to keep their ends against the skin would drive the wearer mad in less time than it took the doctor to tell his fanciful story. It is worse than fancy. It is utterly incomprehensible that a professional man, with a pair of titles to his name, could conceive and deliberately pen down statements so utterly at variance with the facts. And yet it is upon this patent and unspeakable absurdity that the Jaros underwear, according to Dr. Daniels, depends for its wonderful hygienic value.

As to the comparative weight of the doctor's authority on this subject, the reader can judge from the following juxtaposed passages:

Count Rumford writes:

"I have worn it [flannel] in the hottest climates and in all seasons of the year, and never found the least inconvenience from it. It is the warm bath of perspiration, confined by the linen shirt, wet with sweat, which renders the summer heats of tropical climates so insupportable; but flannel promotes perspiration and favors its evaporation, and evaporation, as is well known, produces positive cold."

Dr. Daniels writes:

"Until recently the only woolen fabric we have been acquainted with practically has been flannel, where the wool is first spun and then woven more or less tightly into a fabric. By this means the value of all the properties which make wool pre-eminent as a clothing fabric is diminished; and laboratory experiments made with wool as it comes from the sheep do not agree with those made on flannel—i. e., spun and woven wool. In order to preserve the absorptive property of wool in the highest degree, the fibers must be arranged with their points against the skin, and not longitudinally, as in a woven fabric."

For instance, like that worn by Count Rumford "in all climates and at all seasons."

There is an enthusiasm in the doctor's laudation of the Jaros underwear—a zeal for its exaltation over all other woolen fabrics—out of all proportion to a just admiration of the actual measure of scientific truth involved. His facts are not the facts, his language is not the language, of science.

As a sample of Dr. Daniels's perspicuity, logic, literary accuracy, scientific discrimination, and erudition, the following paragraph is given entire:

"While citing perfection attained in clothing materials, we are confronted by the Jaeger material, or stockinet, a loosely-knitted flannel, made of pure wool, and comparing most favorably with the pure knitted woolen garments of the old-established and renowned manufacturers, Cartwright & Warner, of England. Carefully selected wool is, no doubt, the great claim for this fabric, which is well as far as it goes. In the Jaros material, on the contrary, we find a practical accomplishment of scientific theories, the caprice of no one scientist having been followed out, and, in contradistinction to 'systems,' in which the professional world finds nothing new, we have a simple, practical, scientific material."

Can anybody tell what the doctor means by "citing perfection in clothing materials"? Is he "confronted by the Jaeger material" as one of the perfections? Very likely, since it compares favorably with the "Cartwright & Warner" materials. If the Jaeger material is perfect, what more need be asked? But there is an intimation that the only claim, at least the "great claim for this fabric," is "carefully selected wool." But, again, the doctor has just told us that it is a "loosely knitted flannel," meeting the condition of the "highly porous Jaros material" and the "loose texture" of von Ziemssen, according to Dr. Daniels, that constitutes the sole claim (next to longitudinality) of the Jaros fabric—if a fabric can have a claim?

And what does the doctor mean by his "on the contrary"? What are the contraries in these propositions? Is the "practical accomplishment of scientific theories" (whatever that means) the contrary of "carefully selected wool"? Or is "well as far as it goes" the contrary of "scientific theories"? If not, what? And does the doctor wish us to understand that the Jaros material is the result of the "caprice" of two or more scientists "having been followed out"?

It is not the purpose of this paper to disparage the Jaros underwear, but merely to expose the utter futility of Dr. Daniels's attempt to exalt it into pre-eminence over all other underclothing fabrics, especially the Jaeger flannel, which the doctor seems to think menacingly "confronts" him.

Nor, after the exhibit we have made of Dr. Daniels's facts and logic, will it be considered necessary to vindicate Dr. Jaeger from the former's attempt to belittle the latter in order to magnify the Jaros company.

As an estimate of Dr. Jaeger's work and reputation, we give Dr. Daniels's last paragraph:

"I do not wish to be understood as detracting in the least from Prof. Jaeger's due deserts [*sic!*], for he is entitled to great credit for what he has done in insisting upon the value of wool as a material to be worn next the skin. But he is simply re-echoing what Count Rumford said a century ago, [a part of] which I have already quoted to you this evening. He has founded no new system; he simply insists that pure, fine wool is better than the mixtures we have been using."

Dr. Jaeger simply re-echoes what Count Rumford said a century ago—that is, he "simply insists that pure, fine wool is better than the mixtures we have been using." "Only this and nothing more." Is Dr. Daniels willing to so write himself down as a critic of Dr. Jaeger? If he has read Dr. Jaeger's works, he deliberately misrepresents him; if he has not read them, on what ground does he assume the right to criticise him or to characterize his work?

TROPACOCAINE,

THE NEW LOCAL ANÆSTHETIC,
AND ITS USE IN DISEASES OF THE EYE.

By C. A. VEASEY, M. D.,

CLINICAL ASSISTANT TO THE OPHTHALMOLOGICAL DEPARTMENT OF
THE JEFFERSON MEDICAL COLLEGE HOSPITAL;
CONSULTING OPHTHALMIC SURGEON TO THE PHILADELPHIA LYING-IN CHARITY
AND NURSE-TRAINING SCHOOL, ETC.

TROPACOCAINE, a comparatively new alkaloid recently isolated by Giesel* from a Java coca plant, which has been investigated physiologically by Chadbourne,† is a local anæsthetic somewhat resembling cocaine in its action and yet differing from it in many points.

Chemically it is benzo-pseudo-tropeine, and, according to Chadbourne, is not to be classed with the "true anæsthetics," which cause ischæmia, nor with the "anæsthetica dolorosa" of Liebrich, which cause irritation and hyperæmia, but is to be considered the physiological connecting link between the two classes.

It has been used by Schweigger and Silex, of Berlin, and the former claims to have performed painless iridectomy in less than two minutes after the instillation of one or two drops of a three-per-cent. solution, while the latter has done a tenotomy without any pain in less than a half-minute after an instillation was made.

Desiring to test for myself its action upon the human eye, I have now used it for several weeks almost to the exclusion of cocaine, and in those cases in which I had previously been employing a four-per-cent. solution of cocaine hydrochloride, with the following results:

When first introduced into the eye there was not the marked ischæmia which followed the introduction of cocaine. There was comparatively no smarting—if dissolved in the normal saline solution, and the preparations used by me were three-per-cent. solutions of the hydrochloride of the base made up with $\frac{1}{10}$ -per-cent. solutions of chloride of sodium, as recommended by Schweigger—and in a short time the anæsthesia was complete. As nearly as I could

* *Pharmaceut. Zeitung*, xxxvi, July 4, 1891.

† *Brit. Med. Jour.*, 1892, vii, p. 402.

estimate, the average time from the instillation until complete anæsthesia of the cornea was produced was about two minutes, though the experiments of Chadbourne make the time a little shorter, and the anæsthetic effect lasted about eight minutes, but could be prolonged by repeating the instillations at various intervals.

The pupil was rarely affected, but in a few cases was slightly dilated, the dilatation being maintained for a short time only. In those cases in which there was response from the pupil the "range" of accommodation was slightly changed, the near point being carried farther from the eye. The vision was made slightly hazy, but there was no paralysis of accommodation; and in the cases in which there was no pupillary response there was no change in the accommodation or acuity of vision.

The palpebral fissure was somewhat enlarged, as is the case with cocaine, but at no time did I observe any ptosis.

I have used it in some minor operations, but do not like it any better than the ordinary cocaine solutions; and as the price of the preparation is so high—being about forty cents a grain wholesale—it is hardly probable that it will come into general use.

For removing foreign bodies from the cornea, or for making strong astringent or caustic applications to the cornea or conjunctiva, it is preferable to cocaine on account of its feeble and infrequent action upon the accommodation, thereby preventing the annoyance of a hazy vision for a time; and in cases of keratitis, when an anæsthetic must be employed, it is to be preferred, as it does not diminish to so great an extent the blood supply.

For other purposes I have not found it superior to the cocaine hydrochloride in general use.

125 NORTH SEVENTEENTH STREET.

The Chicago Pasteur Institute.—The director has issued a circular, dated November 18th, giving the results of the preventive inoculations against hydrophobia practiced in this institution since its inauguration on July 2, 1890. Three hundred and two persons have been treated, classified as follows: One hundred and four bitten by animals recognized and ascertained to be rabid by the experimental proof made in the laboratory or by the death of other persons or of animals bitten by the same animal; 126 bitten by animals recognized to be rabid by the symptoms of the disease shown during life; 72 bitten by animals strongly suspected to be rabid; 282 bitten by dogs, 7 by horses, 7 by cats, 3 by skunks, 2 by wolves, and 1 by a mule. The persons treated came from the following States: One hundred and eighty-five from Illinois, 32 from Iowa, 23 from Indiana, 21 from Kansas, 9 from Ohio, 5 from Missouri, 5 from Arizona, 4 from Minnesota, 4 from Michigan, 4 from Louisiana, 8 from Tennessee, 3 from Kentucky, 2 from Texas, 1 from Wisconsin, and 1 from South Dakota. One death was reported among the patients treated, thus giving a mortality of only 0.33 per cent.

The Death of Dr. Charles W. Rush, of the navy, occurred on the 9th inst., at Annapolis. He was appointed from New York in 1883, and was passed assistant surgeon at the time of his final illness, tubercular phthisis. This disease, which was painful and lingering, had been contracted in the tour of professional duty. He was put on the retired list in June, after having been a year on leave.

NEW YORK, SATURDAY, NOVEMBER 25, 1893.

LIFE-SAVING RESULTS OBTAINED THROUGH A STATE
BOARD OF HEALTH.

THE center of all sanitary work in the State of Michigan is its State Board of Health, especially its secretary, Dr. Henry B. Baker. Doubtless there are local health organizations in the State that are doing more or less good work, but Dr. Baker has given shape and force to far the greater part of the sanitary labors in his State, and, if it can be shown that a goodly number of otherwise doomed lives have been saved by those labors, he is deserving of great credit.

The Michigan board began its work in 1874. During the five years previous to that date the average annual death-rate from scarlet fever had been 4.85 in 10,000 inhabitants, but during the fourteen years from 1874 to 1887 the rate was only 2.45 in a 10,000. The rates for small-pox calculated for the same periods of time were 8.5 and 1.9 in 100,000. In the year 1879 a campaign of sanitation against typhoid fever was begun, with the result of saving life, although not in so marked a degree as had apparently been the case in respect to scarlet fever and small-pox. During the decade preceding the establishment of restrictive measures there was an average annual death-rate from typhoid fever of 3.77 in 10,000, while in the decade next ensuing the rate was 3.08 in 10,000.

These statistics are a satisfactory vindication of State board efforts for the prevention of infectious-disease mortality, although the figures are of necessity somewhat small during the earlier years of a restrictive campaign, by reason of the imperfections that attend the inception of such reforms. Apart from considerations as to incomplete plans and a want of experience as to how far it is best to push them, there are those other disadvantages, in the early years of such movements, that flow from want of sympathy and co-operation on the part of others. After a time, when the good results have been demonstrated, it becomes easier to devise and execute such life-saving measures; then the statistics may be expected to make a better showing.

It is the board's purpose to attack consumption in the same way, beginning with the issue of special circulars of information and instruction. Not fewer than 2,500 deaths by consumption occur yearly in Michigan, and it is believed that this mortality can be materially diminished by intelligent measures of prevention, and by educating the people of the State as to the ways by which the disease is spread. On the 30th of September the board unanimously declared consumption to be a dangerous communicable disease and one that must be reported by physicians and householders to the several local boards of health.

Respecting the comparative results obtained in different parts of Michigan, in some of which restriction of the contagious diseases is carried out, as compared with others where this is not the case, it may be said that in the former class of localities the decrease of mortality is marked, especially from diphtheria and scarlet fever. Thus, in 1889, the average number of cases of diphtheria in each outbreak where isolation and other means of prevention were disregarded was 11·66, and that of deaths 2·63; whereas, in other localities, having the advantage of preventive measures, the average of cases was only 1·56 and that of deaths only 0·22—a notable saving of life. Again, take the record of scarlet fever in 1888; there were 11·87 cases of that disease in each outbreak, with an average of 0·54 deaths by that cause, in sections not observing sanitary precautions, while in the other class of places the number of cases was only 2·22 and that of deaths 0·08.

These examples afford a homely yet convincing kind of proof that prevention "pays," not only in the individual localities, but also in the State at large. The workings of these measures of prevention have been most successful in regard to the causes that sacrifice infant life, the so-called diseases of childhood. These are infectious diseases for the most part, and therefore preventable. And this brings to mind the saying of Sir Lyon Playfair, when writing of the sanitary shortcomings of certain Scottish towns: "The death-rate of children in a district is a sort of hygienic barometer of the surrounding physical and moral atmosphere." The barometer of Michigan may be said to be a rising one. Dr. Playfair has defended this care for the progeny of the useful classes in a striking way by comparing the elaborate work that is done by government for the orphan and deficient classes. He has said: "We are not always neglectful. Sometimes we look upon the human infant as a dangerous animal that may turn round and bite us when it grows up." This is said of the child of the dangerous classes. But the children of the productive classes receive no such State care and may grow up dwarfed and relatively unproductive, because civic conditions of overcrowding and ignorance have been permitted to have sway in or about their homes. "If we succeed in getting the homes of our working classes as healthful as the cell of the felon, and surely that should not be considered an unattainable luxury, eight years would be added to the productive ability of our working population."

Let us consider for a moment the money cost to the State of Michigan of the saving of life above referred to. If we mistake not, the average annual cost in twenty years has not exceeded five thousand dollars, inclusive of the salary of the secretary, but exclusive of the printed reports. For a number of years four thousand dollars was the limit of expenditures; afterward the limit was raised to six thousand dollars. The salary of the secretary was two thousand dollars for a number of years, but it has been more liberal in recent years. When we compare this slender outlay with the board's notable achievements it is manifest that few investments have been more profitable to the taxpayer or more creditable to the underpaid, hard-working official.

THE INCONSIDERATE DISMEMBERMENT OF HOSPITAL STAFFS.

At a recent meeting of the Academy of Medicine, Dr. John A. Wyeth spoke upon the subject of the unceremonious dismissal of a member of the visiting staff of the New York Infant Asylum. Dr. Wyeth's expressions appear to us to be dispassionate, moderate, almost judicial in tone. He is reported to have said:

"Within a few months a reputable physician, a member of the Academy, one of the visiting staff of the Infant Asylum, after years of faithful service, was by the president of the board of managers dismissed from the service and another physician appointed to fill his place. No charges of any character were preferred against this physician. There was no question as to his qualification for his faithful performance of his duties. The medical board, which is held responsible for the welfare of the inmates of this institution, was not consulted, either as to the dismissal of this gentleman or as to the appointment of his successor. The medical board, with becoming dignity and self-respect, protested against this action of the managers, and being informed that if they did not like it they could resign, they did resign. I am not one of those who believe in the infallibility of the medical profession. On the contrary, I think they are very fallible and very often wrong, especially in their proneness to suspect an affront to their position or calling when none is intended. I think the gentlemen of the laity who devote their time and money to the support and management of these great charities, in connection with which so many of us labor, are deserving of the utmost praise and consideration and are not second in unselfishness to ourselves. But I do think that in this particular instance an honorable and devoted medical staff have been treated with such disrespect as to amount to an insult to themselves, to the profession in which they have had honorable careers, and that we as a body should resent it. I hold that a principle is at stake—a principle which it is necessary to maintain, not only for our standing in this community (and this I consider of secondary importance), but for the best interests of that unfortunate class, the poor and helpless patients who come under our professional care at the hospitals."

Dr. Wyeth's views were indorsed by many others who took part in the discussion, but for reasons of expediency the Academy did not adopt any resolutions of protest or censure. The members of the medical profession, whose chief solicitude is to see their sick charges do well, are quite content if they receive decent treatment by the laity; they do not exact homage or respect or deference, and a few expressions of gratitude will ordinarily be held to outweigh years of faithful service.

MINOR PARAGRAPHS.

THE TREATMENT OF INTUSSUSCEPTION.

At a meeting of the Pædiatric Section of the New York Academy of Medicine, held on November 9th, Dr. W. E. Forest spoke very strongly against resorting to laparotomy for

intussusception until a thorough attempt had been made at reduction by means of injections. A simple rectal injection, he said, in which the water flowed away as fast as it entered the bowel, was not sufficient, neither were injections by means of a bulb syringe, or any other apparatus by which the pressure could not be regulated, to be relied upon. The use of a siphon of Vichy water had been frequently advised. This was a very unsafe procedure in ordinary hands. The pressure in some siphons was enormous. If the whole force was applied at once to the bowel, it might easily cause rupture. He had performed a careful series of experiments to determine how much pressure the wall of the intestine in health would sustain. He had found that a pressure of eight pounds to the square inch was borne without rupture, and that one of six pounds was perfectly safe. In young children practically every case of intestinal obstruction was a case of intussusception, and in almost every case the intussusception affected the colon. Pressure from above would increase the difficulty. Pressure from below was the only means of reduction. The pressure must be steady, slow, and continuously applied for at least half an hour at a time before attempts at reduction were abandoned. Such pressure did more than could be accomplished by the hands of the operator applied externally. It was applied in every direction; hence the tissues which bounded the invaginated portion of the bowel received their full share of the pressure and were distended, making it much easier for the constricted portion to return to its normal position. It was also elastic pressure, and was not applied along certain narrow lines as in reduction by hand. For obtaining this pressure a fountain syringe should be used. The tip should be bound with bandage to produce a cone-like projection which should fully occlude the rectum. He had found by experiment that each time the bag was elevated two feet and four inches a pressure of one pound to the square inch was added at the outlet. The bag might be held fully twelve or fourteen feet above the patient. Much less pressure, however, should be tried at first. A pressure of six pounds might safely be applied during the first twenty-four or thirty-six hours. After that time it was not safe. Peritonitis, with adhesions and spots of softening, might be formed which would render the use of too much pressure dangerous. He had applied this method in five cases, and in four of them successfully.

EXTERNAL APPLICATIONS OF GUAIACOL IN TUBERCULOSIS.

In a recent issue of the *Medical Week* Professor R. Lépine presents the following conclusions regarding the endermic application of pure guaiacol: 1. External applications of guaiacol are likely to prove extremely useful in certain cases of pyrexia of tubercular origin. 2. The application of from one to two cubic centimetres is practically devoid of all risk of collapse, provided the tubercular process has not reached the stage of supuration and cavity-formation. In the latter case two grammes may cause death, as in a patient under Dr. Bard's observation. 3. Except in cases of extreme irritability of the skin, the application of pure guaiacol is never followed by any inflammatory reaction. 4. The only disadvantages of this method in the earlier stages of pulmonary tuberculosis are profuse sweating, with or without shivering, and a few other symptoms of a very mild description, so that this remedy is to be preferred to antipyrine and even to acetanilide in many cases of phthisis, especially as it has no deleterious influence on digestion. Dr. Lépine agrees with Bard that guaiacol is absolutely without effect on patients suffering from hectic fever due to successive exacerbations of the pneumonic process or to the presence of suppurating ulcerations. On the other hand, it produces a powerful and lasting effect in cases of simple tuber-

cular pyrexia, due to the formation of successive crops of granuloma; in short, whenever the fever is not due to septic infection superadded to the tubercular process. The influence of the guaiacol is largely to be referred to a reflex action on the nerve centers through the peripheral nerve endings, as experiments have demonstrated that the temperature is not affected in animals if the site of application is previously anaesthetized.

THE PROTECTION OF ASYLUMS AGAINST FIRE.

THE asylum branch, at St. Johnland, of the Kings County charities has been reported to be imperfectly guarded against fire. Although the chief buildings comprised in the branch asylum have cost upward of a million of dollars, they have shingle roofs and are within the reach of forest flames. The buildings have hitherto been inadequately supplied with extinguishers. There is a good water supply within reach, and it is now proposed to introduce one or two four-wheeled engines that can be drawn by horses. Extinguishers will soon be placed throughout the corridors of the buildings. This duty of providing the amplest means of fire extinction is an all important one, resting upon trustees, commissioners, wardens, and others, but it is one that is very often deferred, overlooked, and slighted by officials. The newly-appointed commissioners of charities in Kings County have been the officials who have been active in the improvement of which we here write, and they deserve commendation for what they have done. We hold that the medical officials in our various asylums and similar institutions are measurably responsible—although not to the same extent possibly as the executive officials—for the dangerous surroundings of the patients in respect to fire, panic, and the like. We would urge all medical boards to appoint a subcommittee of safety, whose duty it should be to keep records of reported defects in stairways, fire escapes, water supply, and apparatus for the prevention of loss of life by fire.

MALACINE.

Les Nouveaux remèdes for October contains an article relating to this new drug. Dr. A. Jaquet, of Bâle, has made a study of the therapeutic and physiological action of malacine, and finds it an excellent remedy in rheumatism and neuralgic affections. As an antipyretic it is superior to any other of the preparations of this series. It is especially suitable to protracted febrile conditions where it is essential that the remedy shall not be depressing. It is derived from the salicylate of phenacetin. It appears in small crystals of a pale-yellowish color, insoluble in water, but soluble in warm alcohol. The stomach will retain the medicament when no other drug can be borne. It is particularly indicated in cases where the temperature is high and the heart much enfeebled. In rheumatism it can be given almost indiscriminately for a long period without any untoward results. In the treatment of habitual headache the remedy can be prescribed without regard to idiosyncrasies. The dose is from twenty to thirty grains, and the physiological effect continues for about six hours.

NEUROSES AND THE MENOPAUSE.

THE *British Medical Journal* for November 4th contains a report of a meeting of the Medical Society of London at which Dr. Savage read a paper with this title. After a very thorough study of the subject, he concludes that there is a special form of insanity peculiar to the climacteric, which is manifested by progressive symptoms, such as delusions of suspicion, deafness, and general domestic incompatibility. It is suggested that the condition is parallel to general paralysis of the insane affecting

the sensory side, and not so fatal as the disease affecting the more organic side of life. The author admits that the menopause is a minor factor in the production of insanity, but says that the number of women afflicted with insanity admitted into asylums at or after the menopause is greater than at any other corresponding period of time. The prognosis is fairly good, especially in cases where there has been no previous attack of insanity. As yet there is no reliable information as to the subsequent mental condition of patients whose ovaries had been removed.

A TRIBUTE TO THE MEDICAL PROFESSION.

At the annual dinner of the New York Chamber of Commerce on the 21st inst., President Smith, in his opening address, made an acknowledgment of the important aid that had been rendered to the Chamber by the Advisory Committee of Physicians of the New York Academy of Medicine, and paid a graceful tribute to the medical profession in his statement: "It is not too much to say that there is no body of men in the city of New York who give so freely and gratuitously of their time and services to the poor and suffering as do the medical men of New York. If, in the final analysis of human actions, character is the standard of success or failure, then the physicians of New York deserve to wear the laurel wreath."

THE BACTERIOLOGY OF BANK-NOTES AGAIN.

The *Wiener medicinische Wochenschrift* states that the microbe-carrying properties of bank bills have recently been reported upon by two Viennese biologists. The average of a number of examinations of much-handled bank-notes showed that not far from twenty thousand microbes existed on each note. Eight of these were identified as pathogenic, inclusive of the streptococcus of erysipelas, the bacillus of diphtheria, and that of tuberculosis. One of the micro-organisms, not identified with any of the better-known disease germs, was lethal to animals on inoculation.

"ENGLISH CHOLERA."

A recent number of the *Lancet* contains the description of a case of simple cholera the symptoms of which were identical with those of Asiatic cholera. The patient when received at the hospital was in a state of profound collapse. Microscopical examinations of the dejecta had failed to reveal any comma bacilli. Dr. E. A. Snape, who reported the case, said that the close clinical resemblance of such cases with Asiatic cholera pointed out the extreme importance of a bacteriological examination in every suspicious case, for without it an accurate diagnosis was impossible.

ITEMS, ETC.

The late Dr. John C. Peters.—At a meeting of the New York Pathological Society held on Wednesday evening of this week the following resolutions were adopted:

Whereas, It becomes our painful duty to announce the death of Dr. John C. Peters, a founder of the New York Pathological Society, a former president, and for a long period an editor of its *Transactions*; therefore be it

Resolved, That this society desires to place on record its appreciation of his long and valuable services in the different offices in which he served during a period of nearly half a century of continuous membership.

Resolved, That from the first meeting of this society until

his last attendance he has been a tried and faithful servant of its best interests, an ardent promoter of its highest aims, and an active participant in all its progressive doings.

Resolved, That his untiring zeal in the performance of his multifarious duties, his constant courtesy in discussion, his painstaking accuracy of observation, and his ever-available and profound knowledge were qualities that commanded the highest respect of his associates and stimulated the emulation of all who shared the results of his unselfish labors.

Resolved, That the remembrance of his genial disposition, modest manner, energetic spirit, and scholarly attainments will ever serve as a cherished lesson from the well-ordered life of a cultured gentleman, an honored citizen, and a model physician.

GEORGE F. SHRADY, M. D.,

[Signed.]

JOHN H. HINTON, M. D.,

LEWIS A. SAYRE, M. D.,

Committee.

The Medical and Surgical Society of Baltimore.—The programme for the meeting of Thursday evening, the 23d inst., included the following titles: The Theory and Praxis of the Counter-environmental Treatment of Tuberculosis, by Dr. William J. McDowell; Amœbic Dysentery, by Dr. David Streett; Hepatic Abscess, by Dr. J. W. Chambers; and Syphilis, with the Report of a Rare Case with the Primary Lesion in the Nose, by Dr. F. C. Bressler.

The University of Vienna.—The *Wiener klinische Wochenschrift* announces that Dr. M. Kaposi and Dr. J. Neumann have been made ordinary professors of dermatology and syphilography.

The Clinical Society of the New York Post-graduate Medical School and Hospital.—The special order for the meeting of last Saturday evening, the 18th inst., was a paper on The Treatment of Varicocele, by Dr. William B. De Garmo.

The New York Academy of Medicine.—The anniversary discourse will be delivered on Wednesday evening, the 29th inst., by Dr. William H. Thomson, on Modern Experimental Medicine.

Women Physicians in Turkey, according to a dispatch to the *Independent*, have recently been accorded official recognition, largely as the result, it is said, of the American minister's efforts in their behalf.

Changes of Address.—Dr. George W. Caldwell, to No. 45 East Forty-first Street; Dr. Charles T. Poore, to No. 43 West Fifty-third Street.

The Death of Dr. Hermann Hagen, Professor of Entomology at Harvard University, occurred on the 9th inst. He was a medical graduate and for many years a practitioner in Königsberg, Germany. When about fifty years of age he came to America to assume charge of the entomological collections in the Agassiz Museum. His age was seventy-six years. He was a leading authority in the subject of entomology and a member of many learned societies.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 12 to November 18, 1893:*

BREWER, MADISON M., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month on surgeon's certificate of disability, with permission to go beyond the limits of the department.

MUNN, CURTIS E., Major and Surgeon. The leave of absence granted is extended two months.

BIRMINGHAM, HENRY P., Captain and Assistant Surgeon. The leave of absence granted is further extended one month.

FLAGG, CHARLES E. B., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of twenty days.

GREENLEAF, CHARLES R., Lieutenant Colonel and Deputy Surgeon General, is relieved from duty in the office of the Surgeon General of the Army, and will repair to San Francisco, California, and assume charge of the medical supply depot in that city, relieving WRIGHT, JOSEPH P., Lieutenant Colonel and Deputy Surgeon General, who, upon being thus relieved, will repair to St. Louis, Missouri, and assume charge of the medical supply depot in that city.

Marine-Hospital Service.—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Four Weeks ending November 18, 1893:*

PURVIANCE, GEORGE, Surgeon. To report at Bureau for temporary duty. November 7, 1893. To inspect Reedy Island Quarantine. November 14, 1893.

CARTER, H. R., Surgeon. To proceed to Jessup, Ga., for temporary duty. November 10, 1893.

BANKS, C. E., Passed Assistant Surgeon. To rejoin station, Portland, Me. November 3, 1893.

BROOKS, S. D., Passed Assistant Surgeon. To inspect service at Ashtabula, O., and then to rejoin station, Cleveland, O. November 13, 1893.

McINTOSH, W. P., Passed Assistant Surgeon. Granted leave of absence for twenty-three days. November 17, 1893.

MAGRUDER, G. M., Passed Assistant Surgeon. Granted leave of absence for thirty days. November 1, 1893. To proceed to New Orleans for duty. November 15, 1893.

GOODWIN, H. T., Passed Assistant Surgeon. Leave of absence extended thirty days. October 24, 1893.

CORE, J. O., Passed Assistant Surgeon. Leave of absence extended twenty days. November 14, 1893.

GUITÉRAS, G. M., Passed Assistant Surgeon. Granted leave of absence for thirty days. November 14, 1893.

PERRY, J. C., Passed Assistant Surgeon. To rejoin station, Vineyard Haven, Mass. November 3, 1893.

STEWART, W. J. S., Assistant Surgeon. To proceed to Reedy Island and Delaware Breakwater Quarantine Stations for temporary duty.

STRAYER, EDGAR, Assistant Surgeon. To rejoin station, Boston, Mass. November 3, 1893.

Society Meetings for the Coming Week:

MONDAY, November 27th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, November 28th: New York Dermatological Society (private); New York Otological Society (private); New York Academy of Medicine (Section in Laryngology and Rhinology); Buffalo Obstetrical Society; Boston Society of Medical Sciences (private).

WEDNESDAY, November 29th: New York Academy of Medicine (anniversary discourse); Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield).

FRIDAY, December 1st: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, December 2d: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Answers to Correspondents:

No. 418.—We have no knowledge of such a practice.

Letters to the Editor.

PUERPERAL ECLAMPSIA.

BUFFALO, November 19, 1893.

To the Editor of the New York Medical Journal:

Sir: In the *New York Medical Journal* for November 18th is an article entitled *A Case of Puerperal Eclampsia at Eight Months and a Half of Pregnancy*, etc., by R. R. Ball, M. D.

May I be permitted to give Dr. Ball some advice as to a procedure that, I think, might have prevented the eclamptic attack in his patient?

In the first place, I should blame her "regular physician," who left her in Dr. Ball's hands, for allowing her to get into the condition in which she was at that time. A careful examination, every two weeks during pregnancy, of the twenty-four hours' excretion of urine will enable us to prevent the development of such a condition.

During ten years' practice of medicine, with considerable obstetric experience, I have never had a case of eclampsia develop, because I have taken the precaution above mentioned, although in six cases I have found albumin and in four of these casts at various times during the pregnancy. In several others I have found diminished urea and even a diminished amount of urine without casts or albumin. In all such cases it is my plan to make use of alkaline mineral waters and potassium acetate, as well as of the saline cathartics, just as Dr. Ball did; but the procedure which has done more than any of these to relieve the uræmic condition has been the use of the steam or the hot-air bath in the manner described in the article on *The Treatment of Renal Insufficiency* which appeared in the *New York Medical Journal* for July 22, 1893.

In all cases of renal insufficiency the skin is the organ of excretion that does the best work when called into marked activity by means of hot air or steam. In this connection I should advise the reading of a monograph on *Puerperal Eclampsia* published some five or six years ago by G. Veit, of Bonn.

DE LANCEY ROCHESTER, M. D.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, Dr. MORRIS J. ASCH, of New York, in the Chair.

(Continued from page 544.)

A Case of Complete Glottic Spasm in an Adult, followed by Unconsciousness and Prolonged Drowsiness.—Dr. W. P. PORCHER related the history of a case of this affection. (To be published.)

Dr. F. I. KNIGHT, of Boston: I am very much interested in cases like the one related by Dr. Porcher. Some time ago I reported a case and collated others in which there was loss of consciousness after prolonged fits of coughing, and it seemed to me that they were due to a disturbance of the cerebral circulation caused by the coughing. Dr. Porcher does not admit that

in his case the loss of consciousness was due to disturbance of the cerebral circulation, and I am inclined to agree with him, I really think it belongs to a different class of cases, and one of which we have not yet got the proper explanation. These cases are of such rare occurrence that a sufficient number of them have not yet been collated to form any definite opinion regarding them.

Dr. J. WRIGHT, of Brooklyn: These cases, I think, must be very rare indeed. I am not aware of more than half a dozen of them on record. While a hospital interne I saw one of them. The case was brought into the hospital unconscious. The patient was gasping for breath and tracheotomy was rapidly done and artificial respiration maintained. Stimulants were injected and the patient made a tedious recovery. She never had another attack, but has had many sudden attacks of aphonia since, probably due to spasm of the abductors, while her serious attack was evidently due to spasm of the adductors. The case was one of hysteria. If we reject the theory of Krause we must suppose a functional paralysis of the abductors in the first attack and of the adductors in later attacks.

Dr. J. W. GLEITSMANN, of New York: I have collected the literature on this subject and reported a case about two years ago. Altogether I have collected about seventeen or eighteen cases. The case I reported was under my observation several years ago. It was one of laryngeal vertigo produced by coughing in consequence of enlargement of the lingual tonsil. The case was treated in the usual manner, the lingual tonsil being repeatedly canterized. The patient improved remarkably and was cured after four or five applications. He is now a strong, healthy man, weighing about two hundred pounds. The attacks of vertigo caused almost complete unconsciousness and in one of them he fell and injured himself. Hypertrophy of the lingual tonsil was the only morbid condition I could find; this produced the fit of coughing, which was followed by laryngeal vertigo.

Dr. W. E. CASSELBEERY, of Chicago: I recall in this connection two quite interesting cases, which, however, do not correspond exactly with the case that has been related to us by Dr. Porcher. It seems to me that one can divide these cases into different classes, having a certain relationship to each other. First, for instance, cases of reflex spasm of the glottis, to which children are predisposed by the presence of acute laryngitis, but which are oftentimes excited reflexly by irritation of the faucial tonsils, the naso-pharyngeal tonsil, or nasal disease. Closely related conditions may extend into adolescence, an interesting example of which was a girl about fifteen years old, who had enlargement of the faucial tonsils and of the naso-pharyngeal adenoid tissue. In this patient I was able on two occasions to produce typical attacks of laryngeal spasm. She sought relief from such attacks, which would occur spontaneously with frequency and would at times culminate in momentary unconsciousness apparently caused by asphyxia and not by a genuine vertigo. The first experimental seizure I produced accidentally by means of a strong naso pharyngeal spray, reflex laryngeal spasm supervening instantly, the stridulous inspiration and asphyxia lasting about half a minute. The following day, for purposes of investigation, I passed a probe behind the velum and caused it to impinge on the adenoid mass, and she passed again into a violent attack of laryngeal spasm, with unconsciousness, and I was hastily getting out my tracheotomy instruments when she recovered. The attack was so alarming that I discontinued my experimental efforts. The removal of this adenoid mass was possible under cocaine, and complete recovery followed.

In another class of cases there is an attack of vertigo—if we choose to call it so—with absolute unconsciousness and with a

slight twitching of the muscles; this is closely related to epilepsy. Such a case recently came under my observation. There was enormous hypertrophy of the trabeculated bodies from the anterior to the posterior ends, without material enlargement of the tonsils. This patient had never suffered from epilepsy until recently, having reached the age of thirty-eight years, when she began to have attacks of glottic spasm with unconsciousness.

We have, therefore, on one hand, the ordinary cases of spasm of the glottis which we may call reflex. Then, closely associated with this, we have spasm of the glottis with epileptoid movements or *petit mal*, and then again we have the true laryngeal vertigo, with spasm of the glottis and unconsciousness, without epileptoid movements.

I usually attribute these cases to reflex irritation, most frequently arising from the faucial tonsils, the naso-pharynx, or the nasal passage. I believe if the nasal tract and other structures are put in thoroughly healthy condition, or as near as possible to it, it affords the best treatment for these phenomena.

Dr. J. N. MACKENZIE, of Baltimore: I should like to ask whether there were present in Dr. Porcher's case any marked symptoms of a central lesion of the nervous system. It seems to me that we must fall back on a central cause for a full explanation of these cases.

Dr. S. W. LANGMAID, of Boston: I should like to say a few words about the diathesis in these cases of laryngeal vertigo. The reflex may proceed from some portion of the digestive tract. So far as my own small experience goes, I should say that that was the common cause. Undoubtedly there are cases in which the reflex is excited by conditions in the naso-pharynx or the upper respiratory tract, but such have not come under my observation. My experience has been that the laryngeal spasm, both in children and in adults, has arisen from some digestive trouble; this is more especially true in adults. I do not know of a surer way of preventing what was formerly called "false croup" in children than by clearing out the intestines. In many such cases it will be found that the children are subject to intestinal trouble or constipation. When I was in general practice I frequently prevented night calls by instituting a course of treatment directed to the digestive tract, thus successfully preventing the recurrence of croup. Several cases have been reported in local journals of laryngeal spasm in adults, and I have always been able to find that such phenomena occurred in gouty individuals.

Dr. JOHN O. ROE, of Rochester: There is one point in the discussion on this subject that has been overlooked, and that is the irritability and sensitiveness of the larynx itself as a cause of laryngeal spasm. In fact, I have come to consider a sensitive condition of the larynx as the predisposing or exciting cause in all cases of laryngeal spasm, and to believe, as Elsberg observed in a paper read before this society in 1884 on Laryngeal Spasm, that "most of the cases of the heretofore so-called 'laryngeal vertigo' are cases of inspiratory, some of them of deglutitory, adductor spasm."

I have observed cases of both inspiratory and deglutitory spasm of the larynx attended by vertigo. In one case of the latter the patient, a lady of neurotic temperament, was so reduced from inability to take food that she could hardly walk. On attempting to swallow any substance, especially solid food, she would have violent laryngeal spasm, and when I first saw her these attacks were frequently so severe that she could only swallow liquid food which had been strained clear of solid particles. In experimenting with her in regard to the production of the spasm, I found that by touching the larynx lightly with a probe, laryngeal spasm would at once be induced.

There was an inflammatory condition about the arytenoids, which was cured, and the laryngeal spasm was entirely relieved by treatment directed to the larynx. A similar case came under my observation a few days ago, in which solid food could not be swallowed without inducing spasm of the larynx, due entirely to irritation about the arytenoids. I have also seen cases of violent laryngeal spasm from nasal irritation. In one case a man had in his nose a neuroma which, if he attempted to pick his nose, produced a violent laryngeal spasm.

Dr. PORCHER: I feel much gratified that the case reported in my paper has elicited such an exhaustive discussion, particularly as I find the literature on this subject is extremely scanty. There have been so many points brought up that it is almost impossible to comment on each one of them. In my thesis to this association I described a case of spasm of the windpipe. The spasm would apparently be complete, the patient would turn blue in the face and remain so for a few seconds, and then regain control of her breathing. There was no unconsciousness following the attacks, but they were usually preceded by violent paroxysms of cough.

The case referred to in my paper to-day I reported chiefly on account of the unconsciousness and the prolonged drowsiness and torpidity of bowels, which proved to my mind that there was brain implication. I think that Dr. Knight and Dr. Mackenzie have touched the keynote when they attribute the disease to a central lesion. So far as the performance of tracheotomy was concerned, I did not find it necessary to do it. In the case of spasm of the larynx above referred to and published in the *Journal of the American Medical Association** the spasm could be brought on with the utmost ease by titillating the posterior pharynx. In accordance with the recommendations of Dr. Lennox Browne, who advises that the treatment should be directed to the pharynx rather than to the larynx, I applied mild solutions of silver nitrate to the posterior pharyngeal wall, and succeeded in gaining such control over it that the spasms did not return. The only case similar to mine, excepting that there was no history of prolonged drowsiness, was the one reported by Dr. Gleitsmann. Dr. Casselberry reported a case in which the spasms were brought on by spraying the throat. I could in my case perhaps have induced the spasms in the same way. My impression is that the exciting cause of the spasm was the introduction of the coffee into the larynx. I am not perfectly certain of that, however; it is simply my impression.

The attacks did not resemble epilepsy, as there was no jerking of the limbs. There was no paralysis of any kind present, nor were there any marked gouty or rheumatic manifestations which I could detect.

(To be continued.)

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of November 7, 1893.

The President, Dr. B. SACHS, in the Chair.

A Demonstration of Lewis's New Method of Staining the Cerebral Cortex.—Dr. IRA VAN GIESON, in a paper on this subject, stated that, notwithstanding our increased knowledge of the structure of the brain cortex, we were still very much in the dark as regarded its finer pathology, for the simple reason that we had not at our command a satisfactory method of showing the finer details of the cortex, and especially the ganglion cells. The ordinary method of examining the brain by immersion in Müller's fluid and subsequent staining with the various dyes was open to many objections. By this method

we gained no knowledge of the finer processes of the ganglion cells or their structure. We could very well imagine, in the light of the wonderful recent advances in cortical histology due to Golgi's methods, the existence of a number of processes in the cortex of the greatest aetiological importance that were entirely hidden from our view by the Müller's-fluid hardening and ordinary staining. Numerous artificial products arose in the hardening process. In staining, after Müller's fluid hardening, we had no view of the ramifications of the nerve cell; we merely saw the cell body. It also induced a change in the volume of the ganglion cells, and, all things taken together, the method was crude when we were searching for any of the finer changes in the cortex, such as we should be led to expect in chorea, epilepsy, etc. Bevan Lewis's new method of staining the cortex was certainly free from these disadvantages. This excellent method had received a very tardy recognition. It was quite simple and did not require much time. Frozen sections of the fresh brain were placed for a few seconds in a solution of osmic acid (one quarter of one per cent.); they were then rinsed in water and stained with aniline blue black (one quarter of one per cent. solution) and again rinsed; they were then allowed to dry on the slide over night. In a section prepared in this way the ganglion cells were free from artificial products, there was no shrinkage, and we got a very much better preserved picture than by Müller's method. The cells were very perfect. Within the past year or two the process of freezing the sections had been much facilitated by the use of carbonic-acid gas and the freezing microtome. [Reference was here made to an article by Dr. Frank B. Mallory in the *Boston Medical and Surgical Journal* for January 26, 1893.] By this process we could freeze a convolution of the brain in three quarters of a minute. The sections were made with an ordinary carpenter's plane.

Dr. Van Gieson exhibited a number of microscopical sections of the brain cortex stained by the method in question. He stated that the literature on this subject could be found in the *American Journal of Insanity* for July, 1892.

Anomalous Cases of General Paresis.—Dr. EDWARD D. FISHER read a paper on this subject. He stated that general paresis might be defined briefly as a disease of the nervous system, especially of the brain, in which pathologically we found a diffuse inflammation of the membranes and cortex of the brain and also of the membranes and systematic tracts of the cord. Typical cases followed a more or less well defined course, the somatic and psychical symptoms going on hand in hand and finally terminating in two or three years in death. Of late years many cases had been reported which differed largely from the ordinary clinical picture. Savage had referred to a type of case in which all the physical signs of the disease were present, but none of the mental or psychical, or only dementia of a simple character. He had found that the course of the disease might often in these cases be protracted, extending over many years. Dr. Fisher said it was not an infrequent experience to have our diagnosis disputed, both by the friends and by the physician in attendance, in this form of the disease, especially as, under proper care, improvement took place, and because the disease was so long protracted. There might in the future be subdivisions made of the general disease as the symptomatology and pathology were better understood. It had suggested itself to the writer that when either alcohol or syphilis seemed to be a prominent exciting or aetiological factor, the so called somatic symptoms were usually the most marked. Another explanation of these cases might be that the prodromal stage was protracted. In fact, the disease as a rule long antedated its first recognition by the friends and the physician. In mental diseases the emotions were probably the first to show evidences of change

* See *Journal of the Am. Med. Assoc.*, vol. xx, Mar. 18, 1893.

This might express itself by undue exhilaration over a slight thing in itself, by depression, by outbursts of irritability, by a disregard for the feelings of others, etc. Or the patient might become careless or show a lack of proper concern in regard to his health or business. On the somatic side we might have evidence of slight motor disturbance, perhaps slight tremor, slowness or clumsiness in speech, or a slightly atactic or spastic gait. In other cases, again, the early symptoms might indicate hypochondriasis, only later on to develop with rapid strides into well-defined general paresis. Dr. Fisher then gave the histories of a few cases of general paresis that had come under his observation which had pursued an anomalous course. In the first case the disease had extended over a period of at least nine years, and in all probability much longer. The second case was that of a man aged thirty-eight years; excepting that he was rather forgetful and had lost interest in his personal affairs to a large extent, no mental symptoms were present. The man had the peculiar fatuous expression common to the disease; there were some tremor of the tongue and slight tremor of the face, the speech was clumsy, and he had had two or three attacks of aphasia of short duration, lasting from several hours to a day. At times there appeared to be great improvement in his condition. This would probably prove to be one of the prolonged types of cases. The man was still under observation.

Dr. Fisher said that, considering these cases and many others to which he could refer in which the course of the disease seemed to be almost arrested or even had not commenced in the usual manner, it must be seen that general paresis, at least in some cases, might be much altered in its course—to such an extent, indeed, as to make the diagnosis doubtful. Some dementia, however, he thought always existed in these cases. Even in the early stages of a classical case, with exaggerated ideas of wealth and ability, we recognized the inconsequence of ideas and responsibility so essentially characteristic of dementia. This latter condition became more apparent if these patients were allowed to engage in their ordinary vocations. It would often be seen when they were removed from hospital care and permitted to resume their business, when improvement took place physically and mentally, that the course of the disease became a rapid one toward physical exhaustion and dementia.

The Relation of Syphilis to General Paresis.—Dr. FREDERICK PETERSON opened a discussion on this subject with a paper. He stated that the question of the position taken by syphilis in the etiology of dementia paralytica was one that had been attracting great attention among syphilologists and alienists of late years. No fewer than seventy authors had contributed to the elucidation of this problem. The majority of these contributions treated of the subject from a statistical standpoint, and it would seem that sufficient data had been collected to fully satisfy all inquiries regarding that particular. Naturally, the first point upon which precise information was needed was as to the percentage of cases of general paralysis with a history of syphilis, and we were now in a position to supply it fully. Although these statistics had differed very materially at times, yet the results in the main agreed. The figures ranged from as low as thirteen per cent. to as high as eighty-eight per cent. Kjellberg had taken the stand that all cases of general paralysis were of syphilitic origin; that the patients were affected either congenitally or through acquisition. This author stood quite alone in his assertion, which was not justified by observation or facts.

Dr. Peterson said his own statistics on this point were rather questionable, as were all obtained from large public asylums to which patients were taken in stages of the disease too far advanced for them to give trustworthy information regarding themselves, and whither they were generally brought

by relatives or officers unacquainted with such an etiological factor in their histories. There had been admitted into the Hudson River State Hospital for the Insane two hundred and eighty-seven patients with general paresis. In fifty-five of these syphilis had been definitely ascertained to have preceded the disorder. In the remaining two hundred and thirty-two it had been either absent or unascertainable. Actually, then, only nineteen per cent. had been found to be syphilitic; but, assuming that one half the others had been affected, the total ratio would be in the neighborhood of sixty per cent. of the cases. At public dispensaries we saw these cases in the earliest stages, when histories might be obtained more exactly. At the Vanderbilt Clinic forty cases of general paresis had been observed (definitely syphilitic, ten; definitely not syphilitic, twelve; unascertained, eighteen). Taking the twenty-two cases in which the exact facts had been obtained, we have 45.4 per cent. certainly syphilitic and 54.5 certainly not syphilitic. From an examination of all the figures collected above from various sources, it would perhaps be fair to assume that about from sixty to seventy per cent. of all cases of general paralysis had a syphilitic history. The fact was thus established that syphilis was a striking etiological factor in general paresis, but that from thirty to forty per cent. of the cases were not syphilitic. A much more difficult problem was to determine the exact relationship between syphilis and general paresis. Was syphilis a direct cause or merely a contributing agent? Was paresis in syphilitic cases a post-syphilitic affection, or was previous syphilis merely a predisposing factor? This problem might be examined from several standpoints. In the first place, there were Lewin's rather remarkable statistics of twenty thousand patients with syphilis, one per cent. of whom had become insane and in whom not a single case of general paresis had developed. Then there was the further fact that among the native Egyptians, with whom syphilis was one of the most widespread of disorders, no case of general paresis had as yet been reported. It was significant, by the way, that alcoholism was seldom or never observed among them. Again, from the pathological standpoint, it was well known that the direct invasion of the brain by syphilis was characterized by changes in the blood-vessels, by the formation of gummata, or by diffuse meningeal infiltration. The first and third of these processes was most frequent in and about the base of the brain; the second was more common in the cortical regions. On the other hand, in general paresis there was chronic meningitis of the convexity, with atrophy of the cortex, and the processes in this disease and in syphilis were quite distinct, although there were cases in which a syphilitic meningo-encephalitis might closely simulate dementia paralytica symptomatically.

There were some who argued that tabes and general paresis were frequently associated, and that, tabes being a form of syphilitic disease, general paresis must consequently owe its origin to syphilis. If the two diseases had the same etiological imprint, there ought to be a close correspondence in the percentages of syphilis in relation to each, but the consensus of opinion seemed to be that a history of syphilis was found in only from sixty to seventy per cent. of cases of general paresis, whereas in tabes the percentage ranged, according to different authorities, from eighty to ninety-eight per cent. At the Vanderbilt Clinic, in eighty-three cases of locomotor ataxia, fifty-one had been syphilitic, twenty not syphilitic, and twelve unascertained. Of the seventy-one patients with tabes of whose specific history we had exact data, over seventy-one per cent. had been syphilitic and over twenty-eight per cent. not syphilitic. Among cases equally well studied and from the same sources, then, 45.4 per cent. of general paralytics had been syphilitic and seventy-one per cent. of tabetics. Dr. Peterson

said he did not agree with the statement made by Dr. Sachs in a recent article that there was a very frequent development of tabes after dementia paralytica and of dementia paralytica after tabes. In cases of paralytic dementia with tabetic symptoms the nerve fibers of the posterior columns were often little, if at all, implicated. One of the facts which had been employed against the opinion that general paresis was a late form of syphilitic disease was the absolute futility of antisyphilitic treatment. In every form of cerebral syphilis proper we were often enabled to accomplish a great deal of good by vigorous and systematic treatment, whereas in general paresis, even if the history of syphilis was clear, no appreciable effect was produced by antisyphilitic remedies.

In concluding his paper, Dr. Peterson said that in his opinion dementia paralytica had no immediate or remote relation to syphilis as a direct cause. Syphilis was a common etiological factor, but only in the sense of its being a predisposing cause. It prepared the soil in more than half of the cases for the development of dementia paralytica, this disorder having its direct causes in alcoholism, sexual excesses, and overstrain of the mental functions. The higher nervous elements were rendered prone to degeneration by the antecedent specific disease, which, as was well known, gave rise to a cachexia with changes in the constitution of the blood.

Dr. W. D. GRANGER said that the question of a change in the character of the mental symptoms of paresis from the standard type of the disease was one that had been very much debated and studied, and it looked as though the outcome of it might be that the disease known as general paralysis of the insane would be found to embrace more than one disease, possibly more than two, the distinction being based upon the clinical aspect and the pathological conditions present. The variations from the ordinary type of the disease, as he had observed them, had not been so marked in this country as abroad. Two or three per cent. would probably cover the melancholic form of paresis in this country, while in England, in some of the largest asylums, the number had risen as high as fifteen or twenty per cent. of the patients admitted. He had seen two forms of the melancholic type of paresis; in one of these the delusions, although they had been those of depression in one sense, had been of grand depression. For instance, a patient had been very much depressed with the idea that he was the devil; he would constantly cover his face and head in order to hide his horns, and carry a newspaper behind him in order to prevent his tail from growing. But he had been the biggest devil, the greatest and the wickedest devil that could be imagined. On the other hand, there were cases of general paresis in which there was simply melancholia with no grand delusions. Another anomalous type of paresis was that in which no special symptoms were present, except progressive dementia and a feeling of satisfaction; this type was becoming more and more common. The question whether the disease was lengthening or shortening in its course was very much discussed; many thought that its course was being shortened, while, on the other hand, according to some of the English asylum reports, it was being lengthened. In this country we still commonly saw the typical form of general paresis, and death took place in about thirty months after the full development of the disease.

In regard to the relation of syphilis to general paresis, Dr. Granger said he agreed very closely to the views expressed by Dr. Peterson. Syphilis itself did not cause the disease, and it was very difficult to tell what did cause it. That syphilis was very common in Egypt, and that venereal excess was also very common there, were acknowledged by everybody, and that general paresis was very uncommon there was also true, but other conditions existed there which the world over were fa-

vorable to the non-development of paresis. These natives possessed neither energy nor ambition, and spent most of their time basking in the sun. In the coal regions in England general paresis was quite common, the percentage in the asylums being from thirty to forty; in the adjoining agricultural districts the percentage fell as low as two or three per cent., and yet probably syphilis and intemperance were very common in both these communities. In this country general paresis rose as high as from fifteen to twenty per cent. in the Eastern States, while in the Western and Southwestern States the percentage was very low indeed. Yet syphilis was undoubtedly very common in the latter localities; so was drunkenness; still, general paresis was very infrequent there. It took something besides syphilis or intemperance to produce the disease. In the cities we called it the strain due to high civilization. In the coal regions we called it the laborious and peculiar life. Syphilis, while it did not cause paresis, was undoubtedly a decided factor in its production. As regarded the value of statistics in this connection, the speaker thought it extremely difficult to get accurate statements from the patients who were sent to asylums, and upon these we were usually dependent for our statistics. The history of syphilis often dated back many years and was extremely untrustworthy.

Dr. SAMUEL B. LYON said he had often been struck with the fact that when a history of syphilis was obtained in a case of general paresis the former disease had usually existed a long time ago. Most of the patients stated that they had been treated for the disease and cured, and that they had had no manifestation of it for many years. During the current year seventeen persons with general paresis had been admitted into the Bloomingdale Asylum; of these, twelve had had a pretty clear history of syphilis. In only one of them had the syphilis been as recent as four years previous to the development of the general paresis. In almost all the cases the patients had probably received the modern treatment for syphilis—that is, mercury and the iodides.

Dr. Lyon agreed with the previous speakers that, while syphilis was not the immediate cause of general paresis, it was one of its provoking causes; it produced instability of the brain, which then yielded to other more immediate causes. These same patients who gave a history of syphilis had for many years led liberal lives. The course of the paresis in these cases seemed to be more rapid than in those uncomplicated by syphilis. The speaker said that cases of paresis of long duration were not unknown—indeed, not very infrequent. He had met with one case in which the disease lasted over ten years. Its duration depended on the patient's constitution.

Dr. MATTHEW D. FIELD referred to the unreliability of statistics obtained from patients affected with general paresis. He had never seen a paretic in whom active syphilitic symptoms existed. The history of syphilis obtained was usually an old one. It was generally combined with a history of alcoholic and venereal excesses. He had made inquiries among those engaged in the treatment of venereal diseases and who had followed up their syphilitic patients for many years, and they had informed him that general paresis was not common among such patients, although it did occur. Dr. Field regarded syphilis as a predisposing rather than a precipitating cause of general paresis. This was also true of alcohol. Magnin said that chronic alcoholism always terminated in dementia or general paresis. The Chinese were well known to be syphilitic—at least those in this country; still, he had only observed one case of paresis among them. That case had been a typical one; the patient had imagined he had thousands of acres of land, thousands of dollars, and thousands of wives—all white. The reports of the asylums in California showed many cases of

insanity among the Chinamen, but no form of paresis. In conclusion, Dr. Field referred to the change of type that seemed to be occurring in dementia paralytica.

Dr. JOSEPH COLLINS inquired on what grounds Dr. Fisher had based the statement that in general paresis due to alcoholism or syphilis the somatic symptoms were supposed to be in the ascendancy over the mental. If such a statement was well founded, it was in contradiction to what was true of the other diseases due to these poisons, wherein mental symptoms were well marked. At the International Medical Congress in Washington some years ago Dr. Savage had referred to a variety of paresis wherein the motor and somatic symptoms had been apparently the only symptoms of the disease for quite a long time. Such a case, Dr. Collins said, was now under his observation. As regarded the statement made by Dr. Peterson that cases of paresis were unknown in Egypt, Otto had recently reported sixteen cases of the disease in that country. So far as the relationship between syphilis and general paresis was concerned, Dr. Collins said he was very much in accord with the statements made by Dr. Peterson. His statistics corresponded very closely with those of Jacobson, taken from the St. Hans Asylum, in Denmark, and it appeared to him that such statistics could be relied upon. The patients in that institution came from within the narrow confines of the state, and Jacobson, in making up the statistics, had ferreted out every possible etiological factor by inquiry regarding the patient's antecedents, friends, etc. The statement made by the French syphilographers and also by Sternberg, of St. Hans Asylum, that there could be no general paresis without a history of syphilis was no longer worthy of credence. We had statistics galore at our command, and it was now time to draw such conclusions as could be drawn from figures. Dr. Peterson's statistics, taken from the Vanderbilt Clinic, were very valuable; the cases had been seen early, had apparently been carefully studied, and were sufficient in number to draw conclusions from. We all admitted that in about sixty per cent. of all cases of general paresis a history of syphilis dating back from a year to twenty years could be obtained. What we wanted to know was the way in which syphilis caused general paresis. In one of the specimens presented by Dr. Van Gieson this evening, a section taken from the brain of a general parietic, the microscope showed a large number of cells collected around a blood-vessel, with some of their protoplasmic prolongations destroyed or atrophied. In the early stages of general paresis there was vaso-motor disturbance, not only in the cortex of the brain, but throughout the whole body. Syphilis might act through its sinister manifestations on the blood-vessels. It caused a pathological condition that was favorable to the development of general paresis. If there were other contributing factors—and in nearly all cases there were—they acted as the torch to the pile that had already been prepared.

Dr. RALPH L. PARSONS, referring to the possible relationship between syphilis and general paresis, stated that, so far as his observation and reading went, the tissue changes that occurred in general paresis did not correspond with those that were produced by syphilis. Furthermore, we knew that general paresis occurred in a certain number of cases in which there was no history of syphilis. His own studies of dementia paralytica had led him to think that the more immediate causes of the disease were emotional conditions, or one might say congestion of the capillaries of the cortex due to overexertion or overstimulation of the nerve cells of the cortex. Syphilis sometimes caused a degeneration of the nerve tissue, but in opposition to this we observed that general paresis occurred usually during the most vigorous period of life. Dr. Parsons said that, while he felt unwilling to make the statement that

there was no possible relationship between syphilis and paresis as cause and effect, such causative relation had not yet been proved.

Dr. WILLIAM M. LESZYNSKY said that in patients who had died from general paresis it had seemed to him that the pathological changes found in the brain had been very much the same in those who gave a history of syphilis and in those in whom a specific history could be positively excluded. Dr. Hinckley, of the Essex County Asylum, at Newark, N. J., had recently sent him some statistics in connection with this subject. The asylum had about five hundred inmates. During the past eight or ten years fifteen cases of general paresis had been received there. Of these, thirteen had been in males and two in females. In only two of these cases had a history of syphilis been obtained, and in those there had been no somatic manifestations of the disease. The causes given in the remaining thirteen cases were alcoholism, overwork, anxiety, etc. In conclusion, Dr. Leszynsky said he agreed with Dr. Peterson in considering syphilis only as a predisposing factor in the production of general paresis.

Dr. A. D. ROCKWELL referred to certain cases of general paresis that had come under his observation in which the patients for temporary periods had been extremely wretched, utterly disregarding all rules of tidiness and decency, but these manifestations after a number of weeks had passed away and the patients had become quite reasonable again.

Dr. C. H. BROWN said he regarded general paresis as a disease of evolution; syphilis, alcoholism, sexual excesses, etc., were merely complications or predisposing factors. He also referred to the difficulty of getting a reliable history of syphilis in these cases.

Dr. FISHER, in reply to Dr. Collins's question as to the ascendancy of the somatic over the mental symptoms in certain cases of general paresis, said he had referred to cases where there was extreme alcoholism or a recent history of syphilis. In such cases, too, there was frequently a more rapid response to treatment; however, they did not, as a rule, go on to complete recovery. While the old typical cases of general paresis were still the ones usually met with, yet anomalous cases were not infrequent. These perhaps in the past would not have been classed as general paresis. He agreed with Dr. Peterson in regarding syphilis simply as a predisposing factor. In cerebral syphilis there might be many symptoms similar to those of general paresis, but the disease did not run a similar course. Asylum reports on this subject must always be regarded with more or less suspicion. In conclusion, Dr. Fisher referred to the futility of antisyphilitic treatment in dementia paralytica.

Dr. J. F. TERRIBERRY referred to the difficulty of properly classifying certain cases in which there were dementia and other symptoms of cortical degeneration.

The PRESIDENT said that too much reliance should not be placed upon the value of statistics in connection with this subject. A few years ago the number of cases of tabes with a syphilitic history had been placed at eighty-seven per cent., and much lower than this by some authorities; now every one was agreed that the figures should have been as high as ninety-two per cent. We all admitted the frequency of syphilis in general paresis, but the majority of the speakers had laid too little stress upon it as a predisposing cause; they had referred to it as the lesser cause. The speaker said he did not agree with them in this. In other mental diseases, in which heredity played an important part, that factor was regarded as a predisposing cause, while an emotional element was regarded as the exciting cause, but the hereditary taint was certainly a hundredfold more important than the latter element. He was of the opinion that syphilis played a more important rôle in general paresis

than any other aetiological factor. Other facts went to prove that syphilis played a very important part in dementia paralytica. Probably in every case of general paresis that occurred in early life, that was between the ages of fifteen and twenty-five years, there was a history of syphilis. The general impression seemed to be that the specific history was one of long standing. While this was true in the majority of cases, it was not so always. A striking instance of this had recently come under his observation. A young man of twenty-two, while a student at Heidelberg, contracted syphilis, and six months after infection he was affected with typical general paresis, from which he was still suffering.

As regarded the possible relationship between tabes and general paresis, the speaker said he had seen a number of cases in which the two diseases had rapidly followed each other. In one case the tabes had developed nine months previous to the general paresis; in that case there had been an undoubted history of syphilis. In one class of parietic patients the knee-jerks were much exaggerated, while in another they were below the normal or entirely absent. In these latter cases the probability was that changes in the posterior columns had occurred, closely related to the changes that were found there in posterior spinal sclerosis.

Dr. PETERSON said that, as regarded the statement made by Dr. Collins about the cases of general paresis found in Egypt, he had not seen the article by Otto referred to. Dr. Sandworth, the physician in charge of the asylum at Cairo, had informed him that neither he nor his predecessor, who had been there for many years, had ever seen a case of general paresis in a native Egyptian. The disease had occurred among the Turkish officials in Egypt, but not among the natives.

With regard to Dr. Sachs's statement as to the relationship between tabes and general paresis, it was of course true that there were often tabetic symptoms in general paresis, and that the knee-jerks might be absent. In the majority of cases, however, in which the knee-jerks were absent in the early stage of the disease, they subsequently returned and became exaggerated. Furthermore, no changes were found in the posterior columns after death from general paresis.

SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

Meeting of October 3, 1893.

The President, Dr. FREDERICK H. WIGGIN, in the Chair.

A Clinical Paper on some Cases with Various Interesting Features.—Dr. IRVING S. HAYNES read a paper thus entitled. (To be published.)

I. Complete Inversion of the Uterus.—Dr. C. A. BARROWS said that he had never met with this extremely rare condition. The method of reduction employed by the author was certainly a very rational one, for, if the indentation could be made in the uterus so as to carry up the prominent part of it, the very contraction of the circular fibers of the uterus should help to complete the reduction, just as when one pressed in a small rubber ball, after a certain indentation had been produced, the elasticity of the ball completed the reduction. These cases, he believed, were always due to traction on the umbilical cord, either at the time of delivery, from the cord being abnormally short, or from efforts at delivery of the placenta.

Dr. FLINT recalled a case that had occurred in the hospital of partial inversion of the uterus with the placenta *in situ*. The patient had been a colored woman, and no history bearing on the aetiology could be obtained. When first seen the cord had been hanging between the thighs, and the vagina had been filled with clots. The clots had been removed, and the hand

passed in with the expectation of finding the placenta, but, instead, he had felt the fundus of the uterus with the typical cup-shaped depression. It had been a prolapse of the anterior wall.

II. Fracture of the Radius immediately below the Bicipital Tuberosity.—Dr. PARKER SYMS said he had had no experience with fracture of the radius as high as this. He fully agreed with the author in his statement regarding passive motion. He believed in a period of complete rest, and then in slightly active motion, avoiding passive motion. The results were usually better under this treatment.

Dr. W. R. TOWNSEND said that he had only seen one case of fracture of the humerus high up. Last week he had seen a case of fracture at the elbow joint after union had occurred. It was probably originally a "T" fracture. The patient had done well. As was usual in these cases, the fracture was followed by a limitation of motion. The surgeon in attendance had been using passive motion freely, and so much irritation had followed that it was feared osteitis would supervene. Of course, his treatment had consisted in absolute rest. He had already reported a case in which osteitis had really been set up as a result of ill-judged and frequent passive motion; indeed, the family had been so enthusiastic on the subject of passive motion that he had chloroformed the child three times a week in order that he might carry out this treatment. He had persisted in this treatment against advice of counsel, and the child now had an absolutely ankylosed elbow, although when first seen by the speaker there had been about twenty degrees of motion.

Dr. REGINALD H. SAYRE said that many practitioners, instead of putting the arm in full supination, as common sense would seem to dictate, put it up midway between pronation and supination. Full supination approximated the fragments, while the other method necessarily impaired the motion of the arm independently of the formation of osteophytes.

Regarding the question of movement after fractures, there was a time for movement and a time for rest. Where there was any inflammation present rest should be enjoined, but there were times when rest was too much prolonged. Sometimes in elderly people, for instance, after fractures of the elbow, on the removal of the splints, there was not only stiffness of the elbow joint, but also of the shoulder, wrist, and fingers. He had seen such a case last winter; a fracture of the elbow had been recovered from completely and with good result, but after about six weeks, on removing the splint, all these joints had been ankylosed. It had been supposed at that time that the stiffness would be relieved spontaneously, but after waiting a month or two she had come under his care. He had seen other cases of a similar character. He had obtained excellent results in these cases from properly employed passive motion. It was, of course, not very sensible treatment in a case of moderately inflamed joint where the callus was still new, and the bones not thoroughly united, to move it up and down under an anesthetic three times a week. He had seen a great deal of harm done by the improper performance of passive motion.

It was remarkable how opinion on this subject vacillated. One winter we were told to immobilize the fracture and leave it alone, and another winter we were told that no rest should be given, but the joint should be massaged from the very beginning. We should choose between these extremes. It was undoubtedly true that many uninjured joints did become stiff from various causes after prolonged immobilization. For instance, on removing the splints after a fracture of the femur high up, there was usually stiffness of the knee, which was quite persistent. A cure could be very much hastened by proper mas-

sage and movement. The same was true when fracture had been into joints or their immediate neighborhood. It was a mistake to use too frequent or too violent passive motion when inflammation was still present, or union not yet completed; this, of course, tended to produce an exuberant callus and a filling up of the joint cavity.

Dr. HAYNES said that the bodily functions of old people were at a low ebb, and these subjects were prone to get up ankylosis. Besides this, old people were often either rheumatic or gouty, and required constitutional as well as surgical treatment.

We could draw no reliable rules of action from treatment based on experience with old people; we should be rather guided by the results of treatment of young adults or children. The tendency to ankylosis among old people might be avoided, not only by constitutional treatment, but by avoiding unnecessary immobilization of other joints than those directly injured. For instance, in a Colles's fracture he thought it was a mistake to carry the splint down below the wrist joint; from the very first the parts below the wrist should be left perfectly free. This plan would give the best motion. If, on the other hand, they were kept at rest, the tendons were bound down and the stiffness would last for a considerable period.

III. *Intestino-peritoneal Septicæmia*.—Dr. BARROWS asked if there was any laceration of the cervix.

Dr. HAYNES answered that no speculum examination had been made, but there had been no hæmorrhage to indicate such an occurrence.

Dr. BARROWS thought that in most of these cases the avenue of entrance was in the parturient canal, usually at the cervix; for this reason he always carefully examined the os and closed any tear that might be found.

He was interested in the theory of intestino peritoneal infection advanced by the author, for it might be very convenient for all of us to fall back upon. He cited a case in his practice in which there had been a normal temperature for ten days after confinement, and no odor to the discharge; then there had been a chill, followed by acute endometritis and metritis. The interior of the uterus being found in a foul condition, it had been curetted.

Dr. PARKER SYMS agreed with the preceding speaker about cases of this kind. Whenever there was an elevation of temperature after confinement, he always suspected the uterus at once, and he thought in the majority of cases it would be found that the uterus was infected. He also believed that in many glandular inflammations of the breast the trouble originated in the uterus, due to a mild form of sepsis. He was sure he had seen such cases.

Dr. GEORGE P. BIGGS asked why the term "intestino-peritoneal septicæmia" was used. He understood there was simply a fever and no symptoms indicating the involvement of the peritonæum.

Dr. W. N. HUBBARD said he was very glad to hear Dr. Barrows say that infection might occur after the tenth day, for, although this was his own belief, a large number of physicians were inclined to believe that fever occurring after the fifth day was not usually septic, but due to malaria or some other like cause.

Dr. R. H. SAYRE saw no reason why a patient should not have a normal temperature for a week or ten days, and then show signs of sepsis. He recalled a case in which he had amputated the thigh for an osteomyelitis. There had been an absolutely normal temperature for seven days, but on the eighth day there had been a chill, and the temperature had risen to 102°. On removing the dressings, he had found that the central canal had become infected, and he had been obliged to reamputate at a higher level.

Dr. BARROWS referred to a case occurring in the practice of an intimate friend. A woman had had an absolutely normal temperature for the first nine days, and on the tenth day the physician, a well-known obstetrician, had assured her that she was safe. That same evening she had had a chill, developed sepsis, and died. An examination of the uterus had showed septic inflammation.

A woman might have a slight laceration of the cervix which was consequently bathed in the lochia; hence, if some infection entered the vagina and decomposition took place, the septic matter usually entered the lymphatics through this laceration, and not by an extension into the uterus as an endometritis.

Dr. HAYNES said if he had to accept Dr. Barrows's statement *in toto* there would be some elements lacking; for instance, there should have been some foul discharge from the uterus in his case, yet no septic matter had been removed from the uterus by the curette. He could not now recall the condition of the abdomen, and therefore could not say whether or not there had been symptoms of peritonitis.

Dr. BARROWS remarked that the point he desired to emphasize was that the infection might pass through the lymphatics in and about the cervix to the broad ligament and the peritonæum; hence, the uterus might be perfectly sweet in the early stage, and still the patient be really suffering from septicæmia.

Dr. HAYNES said he had read in some reports of the Obstetrical Society of New York that following certain laparotomies there had been intestinal paralysis, with some elevation of temperature, and that this had been all relieved by saline cathartics. The statement was made there that the inflammation was due to the bacilli in the intestine.

IV. *Ventral Hernia*.—Dr. BARROWS said that these cases of ventral hernia were extremely interesting because of the difficulty of effecting a cure. He had seen quite a large number of these cases in women, and he had recently operated upon two or three very large ones in which an incision had been made five or six inches long, and the whole linea alba had been found converted into a cribriform plate—*i. e.*, filled with small openings through which the hernia came. It was better to take out a large V-shaped piece of this fascia, and then separate the planes of the abdominal wall, first bringing together the peritonæum with catgut. Then the fascia should be separated from the muscle, fat, and skin above. He had gone back even three or four inches from the free edge to separate it freely. The homologous structures were brought together very carefully with interrupted sutures of stout catgut. This admitted of the normal motion occurring between the structures composing the abdominal wall. Before adopting this method all his cases had relapsed quickly, but since then he had had one case without relapse after two years, and two or three with no relapse after one year.

Dr. HAYNES said that his patient had also remained well for two years, and possibly might still be well had she not abandoned the abdominal supporter after wearing it for about six months.

Book Notices.

Burdett's Hospital Annual and Year Book of Philanthropy, 1893. Containing a Review of the Position and Requirements and Chapters on the Cost of Management of the Voluntary Charities, and an Exhaustive Record of Hos-

pital Work for the Year. Edited by HENRY C. BURDETT, Author of Hospitals and Asylums of the World, etc. London: The Scientific Press (Limited), 1893. Pp. xciv-510.

MR. BURDETT's works on hospitals are too well known for any particular mention of this one to be required. It will prove exceedingly useful to everybody who has to do with the management of hospitals, the cost of their maintenance, and their officers.

BOOKS, ETC., RECEIVED.

A Practical Treatise on Materia Medica and Therapeutics. By Roberts Bartholow, M. A., M. D., LL. D., Professor of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College of Philadelphia, etc. Eighth Edition, revised and enlarged. New York: D. Appleton and Company, 1893. Pp. xxvii-820. [Price, \$5.]

The Principles and Practice of Surgery. By John Ashurst, Jr., M. D., Barton Professor of Surgery and Professor of Clinical Surgery in the University of Pennsylvania, etc. Sixth Edition, enlarged and thoroughly revised. With a Colored Plate and Six hundred and Fifty-Six Illustrations in the Text. Philadelphia: Lea Brothers & Co., 1893. Pp. xxviii-33 to 1166. [Price, \$6.]

The Medical Student's Manual of Chemistry. By R. A. Wittenhan, A. M., M. D., Professor of Chemistry and Physics in the University of the City of New York, etc. Fourth Edition. New York: William Wood & Co., 1893. Pp. xiii-543. [Price, \$3.75.]

The Blot upon the Brain: Studies in History and Psychology. By William W. Ireland, M. D., Edinburgh, formerly of H. M. Indian Army, etc. Second Edition. New York: G. P. Putnam's Sons, 1893. Pp. viii-388.

Chemistry and Physics. A Manual for Students and Practitioners. By Joseph Struthers, Ph. B., Columbia College School of Mines, New York; D. W. Ward, Ph. B., Columbia College School of Mines, New York; and Charles H. Willmarth, M. S., New York. Series edited by Bern B. Gallaudet, M. D., Demonstrator of Anatomy, College of Physicians and Surgeons, New York. Philadelphia: Lea Brothers & Co., 1893. Pp. vii-17 to 258. [*The Students' Quiz Series.*]

Handbook of Public Health and Demography. By Edward F. Willoughby, M. D. Lond. London and New York: Macmillan and Co., 1893. Pp. xvi-509. [Price, \$1.50.]

Chirurgie des voies urinaires. Études cliniques par le Dr. E. Louneau, Professeur libre de clinique des maladies des voies urinaires, etc. 2me édition. Revue, augmentée et accompagnée de cinq planches hors texte noires et chromolithographiées. Bordeaux: Feret & fils, 1894. Pp. 300.

Transactions of the American Surgical Association. Volume the Eleventh. Edited by De Forest Willard, M. D., Recorder of the Association. Philadelphia: William J. Dornan, 1893. Pp. xvi-372.

The Prevention of Deafness with Instruments invented by Charles A. Bucklin, A. M., M. D., New York. [Reprinted from the *Medical Record*.]

Aural Vertigo (Ménière's Disease). By L. Harrison Mettler, A. M., M. D., Chicago, Ill. [Reprinted from the *Journal of the American Medical Association*.]

Hemiparaplegia; with Report of a Case completely Recovered after One Year's Duration. By L. Harrison Mettler, A. M., M. D., Chicago, Ill. [Reprinted from the *Journal of the American Medical Association*.]

Address to the Profession and the Public. By Dr. J. T. Graham, of Wytheville, Va. Delivered at the Twenty-fourth Annual Session of the Medical Society of Virginia, at Charlottesville, Tuesday, October 3, 1893.

Transactions of the Medical Society of the State of West Virginia. Twenty-sixth Annual Session, held at Parkersburg, W. Va., June 7, 8, and 9, 1893.

Text-book of Normal Histology: including an Account of the Development of the Tissues and of the Organs. By George A. Piersol, M. D., Professor of Anatomy in the University of Pennsylvania. With Four Hundred and Nine Illustrations, of which Three Hundred and Fifty-eight are from Original Drawings by the Author. Philadelphia: J. B. Lippincott Company, 1893. Pp. xviii-11 to 439. [Price, \$3.50.]

Selected Papers in Gynecology and Obstetrics. By D. Berry Hart, M. D., F. R. C. P. E., etc., late President, Edinburgh Obstetrical Society. Edinburgh and London: W. & A. K. Johnston, 1893. Pp. xiv-239.

Manual of the Diseases Peculiar to Women. By James Oliver, M. D. (Edin.), F. R. S. (Edin.), F. L. S., M. R. C. P. (Lond.), Fellow of the Obstetrical Society of London, etc. London: J. & A. Churchill, 1893. Pp. xi-211.

The Pneumatic Cabinet in the Treatment of Pulmonary Phthisis. (Read before the American Climatological Association, Richfield Springs, New York, June 24, 1892.) By C. E. Quimby, A. M., M. D., New York. [Reprinted from the *International Medical Magazine*.]

Poliomyelitis. By J. T. Eskridge, M. D., Denver, Col. [Reprinted from the *Texas Medical Journal*.]

A Clinical Lecture on, 1. Case of Poliomyelitis. 2. Case of Chorea. 3. Case of Sacro-iliac Arthritis (probably Rheumatic). By J. T. Eskridge, M. D., Denver, Col. [Reprinted from the *Virginia Medical Monthly*.]

The Primary Action of the Galvanic Current. It increases the Amount of Ozone in the Blood as shown by Chemical Test of the Blood in the Arteries—with our Theory of Animal Electricity. By J. Mount Bleyer, M. D., and M. Milton Weill, M. D., of New York city. (Read before the American Electrotherapeutical Association, Chicago, September 12, 1893.)

Report on Nasal Surgery, with Illustrated Cases. By M. F. Coomes, A. M., M. D., Louisville, Ky. [Reprinted from the *American Practitioner and News*.]

A Case of Panophthalmitis, caused by the Bacillus Coli Communis. By Robert L. Randolph, M. D., of Baltimore, Md. [Reprinted from the *American Journal of the Medical Sciences*.]

Annual Report of the Health Officer of the Port of New York. For the Year 1892.

Greichisch als allgemeine Sprache der Aerzte und Gelehrten überhaupt. Zu Rudolf Virchow's Rectoratsrede: "Lernen und Forschen." Von Dr. Achilles Rose. New York: Gustav E. Stechert, 1893.

The Report of the Department of Pathology of the University College, London, 1892-'93. Together with a Collection of Papers and Abstracts published from the Laboratory. Volume I. Edited by Victor Horsley, F. R. S., F. R. C. S., and Rubert Boyce, M. B.

Miscellany.

The Preliminary Education of Medical Students.—In an address to the students of medicine of St. Mungo's College, Glasgow, by Professor R. T. Kent, published in the *Glasgow Medical Journal* for November, we find the following:

"Can any one pretend that a lad sixteen or seventeen years of age who is leaving school, and perhaps not from a very high class in that school, has received such a liberal education

as will qualify him for entrance into one of the so-called learned professions? In some cases, no doubt, he leaves school at even a more tender age and passes a year or so in the hands of some reverend crammer, and by him is duly crammed through one of the preliminary examinations, and this constitutes his liberal education!

"How," you will ask, 'can such a state of affairs be remedied?' Certainly not by any mere raising of the standard in the entrance examinations. The simple fact of having passed an examination in arts, however difficult, is not in itself any evidence of having received a liberal education, and to merely raise the standard of such examinations would be to play into the hands of the crammers. It is not merely the possession of a certain amount of knowledge in such subjects as classics, mathematics, history, etc., which will properly equip a student for his professional work; it is the training he has undergone in acquiring this knowledge in a proper way and not in having it crammed into him in a few months which constitutes a liberal education, and is likely to be of value to him in after-life. Perhaps it would be as well to define more accurately what is meant by a liberal education. I will quote, therefore, the words of one of the deepest thinkers of the century on this subject: 'That process of training by which the intellect, instead of being formed or sacrificed to some particular or accidental purpose, is disciplined for its own sake for the perception of its own proper object and for its own highest culture is called a liberal education.' Now, such an education, such a process of training, can never be insured by the mere passing of an examination. Surely it is somewhat anomalous that all the examining bodies who grant licenses to practice should lay down more or less stringent regulations as to the course of professional study which must have been pursued, while they allow the greatest possible latitude as to the manner in which the general education of their candidates shall have been conducted. Thus we find that so many months must have been spent in attendance upon anatomy lectures, so many on physiology, etc., and yet the preliminary education, so important in itself, may have been acquired anyhow, so long as a certain examination has been passed, and you are all of you familiar with that long list of examinations which are recognized as qualifying examinations in arts.

"Now, this is scarcely consistent! The examining bodies in laying down these regulations have decreed that it is not sufficient for a student when he comes up to be examined to exhibit a certain amount of knowledge, but they require in addition certificates as to how that knowledge has been gained. They require him to be 'signed up,' as the expression goes, for attendance upon a certain number of lectures and for a certain amount of practical work performed under the superintendence of a recognized teacher. In other words, they try to insure as far as possible that in his professional education the student shall have undergone a certain process of training, but as regards the general education of their candidates they are content to let the matter be settled by the mere passing of any one out of a long list of examinations.

"Now, I am certain that every one who has been brought much into contact with medical students will agree with me that there is the widest possible variation in their attainments as far as general knowledge is concerned, and that the present state of affairs with regard to their preliminary education is eminently unsatisfactory. But it is an exceedingly difficult problem to solve to say how matters could be improved. The first step would, I think, be the fixing of an age limit, and it would be very easy to insist that evidence of having attained a certain age should be produced when first registering as a medical student. What that age should be I would not ven-

ture to suggest, but I think there is much to be said in favor of its being advanced considerably beyond the present average. It would no doubt be of great advantage, both to the students themselves and to that of the medical profession generally, if the only entrance to the profession were a degree in arts from a recognized university. But such a regulation as this might perhaps be too severe and might be held to entail somewhat of a hardship.

"Could we, then, without going quite so far as this, insure that every student before commencing his professional studies shall, in addition to merely passing an examination, have undergone a more or less definite training in arts? I think that this might be possible. We may divide the whole community of medical students into two classes: Firstly, those who at the outset of their career have become members of a university with a view to becoming possessors of that much-coveted degree, M. D.; secondly, those who are only working for the license and to whom a degree, whether in arts or in medicine, is either no desideratum or else is quite beyond their power to obtain. This latter class is more numerous in London than here in Scotland, where the facilities for obtaining a degree in medicine are more numerous and the regulations less exacting. Now, with regard to the former class—namely, those who at the outset of their career have become members of a university—I do not think any hardship would be entailed had they been compelled to go through that course of training which qualifies for a degree in arts of their university before commencing their medical studies. In other words, I would make a degree in arts compulsory upon all candidates for a degree in medicine or surgery, and I would undertake to say that under such circumstances there would not be one medical graduate of five years' standing out of a hundred who would, upon looking back, consider that the time spent over his arts course had necessarily been wasted.

"But with my second class of students, who are not members of any university, the problem is much more complicated.

"We can not, as I say, compel them to go to the universities for their general education, and at the same time we are not justified in assuming, because they can produce evidence of having passed a certain examination, that their preliminary education has been such as is desirable for members of a learned profession.

"There only remains, then, it appears to me, one possible alternative, and that is to approximate, as far as possible, the preliminary training of intending medical students to that required for the arts degree of some university. Thus, in place of one examination, to substitute several, and to insure that a certain time shall elapse after one examination has been passed before admission to the succeeding one; to require evidence not only of having passed examinations, but of having undergone a certain definite course of training; and, at the same time, I am of opinion that greater inducements should be held out to students to more thoroughly prepare themselves for their professional training by undergoing a course of instruction in arts at a university.

"I am aware that some concession is already made to graduates in arts and science, who shall have spent a year in the study of physics, chemistry, and biology, and shall have passed an examination in these subjects, by allowing them to count one year of medical study; but such a meager concession as this is not likely to have much effect in drawing students to the universities, and no doubt it is not intended that it should. In London, you know the great bulk of medical students labor under the disadvantage of having no university available which will grant them degrees upon similar terms to those on which

these are obtainable from the Scottish or Irish universities; and to remedy this, it has been proposed to create what I may call a skeleton university, which shall grant degrees to this large body of students without materially altering that course of study which now qualifies for the license. In other words, because the students at the outset of their career have not gone to the universities, a new university is to be created and brought to the students. Now, I can not think that they who are advocating this scheme are doing so from entirely disinterested motives.

"The value of a university degree has generally been considered to depend upon the fact that it entails a certain period of residence, a certain course of instruction and discipline. We must, of course, make an exception—that exception perhaps which proves the rule, in the case of the University of London, the value of whose degrees rests solely upon the high standard of the examinations. But in this proposed university neither was the standard of the examinations to be so high as that of the present London University, nor was any discipline or training to be required further than is already necessary for the license.

"I am strongly of opinion that if greater inducements were held out to medical students to go in for an arts degree at one of the numerous existing universities, and if, at the same time, the course of preliminary instruction for those who are not members of a university were more closely approximated to that required for such a degree, the demand for new universities would very soon cease to exist, or, at all events, would be very considerably diminished.

"The objection, moreover, which is sometimes urged that the older English universities require an expensive residence to qualify for their degrees has really ceased to have any weight, since the institution of what are now known, both at Oxford and at Cambridge, as unattached students.

"There are some here, no doubt, who will be inclined to think that I am placing too much stress on the value of a liberal education to a medical practitioner. 'Of what use is it,' they will say, 'to us to have spent so many years in the study of classics, mathematics, philosophy, etc., if we can not make use of them in our professional work? All the classics in the world will not teach us how to set a fracture, nor all the mathematics how to treat a case of typhoid.'

"But they forget that the medical practitioner has other than merely professional duties to perform, that he is brought into contact with members of other professions, that he becomes their friend, and very often their confidant; and that it is to his advantage to become not only a skillful practitioner, but a wise and useful citizen.

"That man who has received but little education beyond his professional training, no matter how clever he may be, no matter how successful in his treatment, is in great danger of becoming merely what I may describe as an automatic guinea-in-the-slot machine for the cure of diseases.

"I have read," says Sir William Dalby, in Dr. Chesterfield's letters to his son, 'many charmingly written articles and books on surgical matters; but I have also, for my sins, waded through some others that have positively made me shudder. For lumbering, blundering sentences; for hideous grammatical errors; for long paragraphs, whose construction almost makes one giddy; for the jumbling together of a number of Latinized words, and a complete absence of pure English, commend me to the effusions of an illiterate surgeon.'

Whale's Milk.—The following article appeared several years ago in the *Rockland (Maine) Courier-Gazette*:

Whale's milk is now highly recommended for certain dis-

eases. The only difficulty that we can see in carrying out the idea is in getting the milk. Who will milk the whale? Nobody has ever tried it, and it is not known whether or not the moral nature of the whale will permit such liberties being taken. Of course if you could get a whale of good disposition, one that is kind and affectionate by nature, there would be no difficulty; but suppose you run across a whale that is vicious, and just as you get a pail full of milk she flaps her tail around and catches you in the eye, and then steps in the pail? Though, come to think of it, a whale couldn't step in the pail, because she hasn't any feet—but we don't know as that makes any difference, either, for a yardstick has three feet and it can't step in a pail. But really and truly and no joking, we don't see how this whale-milk industry is to be cultivated. Suppose a man wants to go into it for a speculation, and he advertises in advance that he will supply whale's milk to all kinds of invalids at lowest prices, with reduced rates to clubs. It will be his object, of course, to keep a stock of thoroughbred whales, though grades would not be undesirable. In order to get the best stock, he would have to send a vessel after his whales and lasso a brood in their watery fastnesses. Then he'd tow them into port. Then the only way they could be milked, as it looks to us, would be by a diver, and, as sure as you live, if a stranger went poking around a whale in a suit of diving armor, he'd be certain to tickle her, and that would make her laugh, which would be liable to curdle the milk. But how could he milk into a pail under water? The water would run into the pail in that case as freely as it does in ordinary milking on land, and the result would be milk like that in every-day use, with possibly not quite so much water. Nobody is more friendly than we to new industries of this character, and we are glad to encourage anything that will ameliorate the condition of invalids, but the whale-milk business strikes us as being a trifle far-fetched. Better leave the whale to furnish stiffening for women's dress waists, and let its milk accomplishments remain uncultivated.

Primary Abdominal and Ovarian Gestation.—In the November number of the *Edinburgh Medical Journal* there is an article on the etiology of ectopic gestation by Dr. J. C. Webster, assistant to the professor of midwifery and women's diseases in the University of Edinburgh. The author believes that the adoption of views which imply that the ovum can begin its development only on a tissue capable of a special genetic reaction, and therefore only in some portion of the passages developed from the original Müllerian ducts, makes it difficult to believe in the possibility of the occurrence of primary abdominal gestation. Although, owing to the writings of Bland Sutton, Lawson Tait, and Berry Hart, belief in the existence of such gestation has been widely discredited, no well-founded reason has been raised to show why it should not take place. Indeed, he says, considering the factor which these authors had believed to be of chief importance in the development of tubal gestation—namely, inflammation destroying the epithelium of the mucosa—it does not appear, according to that view, why a fertilized ovum may not attach itself and grow on a part of the wall of the abdominal cavity which has lost its superficial covering of cells by reason of the same pathological process. On other grounds, however, the abdominal intraperitoneal development is improbable, because, so far as is known, the peritoneal tissue can not undergo the changes required for the establishment of the necessary relationship with the young ovum. As regards the ovary, there is still greater difficulty. We have no reason to believe that the Graafian vesicles can respond to the genetic influence, and there is no proof that gestation has ever begun in them. Supposed cases of ovarian gestation require to be studied carefully and in every instance to be distinguished from

the following conditions which may be mistaken for it—namely, gestation in the outer end of the Fallopian tube which has become intimately connected with the ovary; gestation in an accessory tube end which has become attached to it; gestation in an ovarian fimbria, which may sometimes be hollow and represent the extreme outer end of the tube; gestation in a tube which has entered into the ovarian sac of peritonæum, which occasionally occurs in the human subject. The primary development of an ovum in the ovarian sac is as improbable, he adds, as its development in relation to any other part of the peritoneal cavities.

Calomel Soap in the Treatment of Syphilis.—In the *Lyon médical* for October 29th there is an abstract of an article by De Watrazewski, credited to the *Revue des sciences médicales*, in which the author says that calomel soap, while it possesses all the advantages of the traditional gray ointment and the more modern gray soaps, is superior to them in the frictional treatment of syphilis because it is free from the objections attaching to them. Its application is easy and takes little time. It is colorless and odorless, and neither soils the clothing nor irritates the skin. It is prepared by mixing the calomel in a state of vapor with a potash soap in the proportion of one to two or one to three. The amount required for a daily friction is from thirty to forty-five grains, containing from seven to ten or fifteen grains of calomel. The friction itself is substantially the same as with ordinary mercurial ointment.

Balsam of Peru in Gastro-intestinal Diseases of Children.—Dr. Nuggia has contributed an article on this subject to the June number of the *Archivio italiano di pediatria*. It appears by a summary of the article given in the *Revue générale de clinique et de thérapeutique* for November 1st that Trouseau and Pidoux had recommended the remedy in gastro-intestinal catarrh, especially in diarrhoea, with or without tenesmus, in typhoid fever, and in infectious dysentery. The author uses the following mixture: From a grain and a half to three grains (for very young infants) or from five to seven grains (for older children) of balsam of Peru, forty-five grains of alcohol, half an ounce of syrup of lemon, and three ounces of water. He reports successful results from the use of this formula, and says that he has not observed any untoward action of the mixture; nevertheless, it is better not to prolong its administration more than three days, not on account of the balsam of Peru, but on account of the alcohol.

A French Surgeon of the Fourteenth Century.—In the *Mercredi médical* for November 1st we find an account of M. Mondeville, surgeon to Philippe le Bel, who wrote in the beginning of the fourteenth century a treatise on surgery which was a remarkable work, deserving of being read at the present day. This book, the oldest on surgery in the French language, was not printed, as it was written in Latin. M. Nicaise has just published a translation of it in order to make it popular. To give an idea of the author and of his advanced views, says the writer of the article, it is enough to recount what he says of suppuration and of the treatment of wounds. He was the first to maintain that suppuration was a complication to be avoided, and that is the doctrine of the present day. From that he deduced the method of treating wounds. He practiced immediate union and used a dressing of hot or salted wine and protected the wounds from the air, for, as we believed a few years ago, he considered air to be the cause of suppuration. He also devised an antiseptic plaster to be applied to wounds. His treatment of wounds of the large intestine will give an idea of the worth of this pioneer surgeon. He closed the wound in the intestine with the glove's suture, replaced the intestine,

and sewed up the abdominal wall, and if, he said, the operation was done immediately after the wound, a cure was rapid. He has effected it with only one dressing. There was, then, in the fourteenth century an epoch of surgery in which it was sought to combat suppuration and in which the immediate union of wounds was practiced, but this period has until now remained unknown because Mondeville's book was not published.

A Curious Case of Prolonged Fasting.—The *Lyon médical* for October 29th cites from *La Médecine moderne* for October 18th a summary of the following case taken from the Russian newspapers: A girl, seventeen years old, was overtaken by night near the village of Ruzino in the government of Moscow, on the 24th of November, 1892. Being afraid to go home in the dark, she decided to pass the night under a hangar covered with a little straw. During the night a snowstorm occurred, and in the morning the girl found herself unable to escape from the load of snow which covered her. The first day she ate five morsels of bread which she had with her. After that she had no other nourishment than the snow which imprisoned her. It was not until the end of fifty-one days that she was discovered under a bank of snow three feet and a half deep. She was then, on January 14, 1893, taken to a hospital. Although completely exhausted and unable to move a limb, she could answer questions and was conscious of what was going on about her. Her skin was cold and pale and there was general anasarca; the mucous membranes were of a striking pallor; no trace was left of the subcutaneous fat, and the muscles were wasted. Her voice was very feeble; her respiration was 26; her pulse was 84, small and weak; her temperature was 100.4° F. The heart sounds were distinct but feeble, and an anæmic souffle was audible in the vessels of the neck; the urine was concentrated, but contained neither sugar nor albumin. For two days she remained in a state of semi-unconsciousness and somnolence, but she made rapid progress and at the end of the first week she could take the ordinary diet of the hospital. If we suppose that the date of her imprisonment in the snow was correctly stated and that she ate all the bread on the first day, the account goes on to say, this involuntary imitator of Succi must have gone from the 24th of November to the 14th of January, exactly fifty days, without taking any nourishment.

A Superior Method of making Tea.—The *Lyon médical* for October 29th gives the substance of an article published in the *Répertoire de pharmacie* for October 10th. The tea is to be powdered immediately before it is used, boiling water is to be poured upon it (water not too hard), and to be left in contact with it for from five to seven minutes. In this way the aroma is developed in a remarkable degree, the theine is completely extracted, and the resulting infusion contains but a minimum of tannin.

The late Professor Leon Le Fort, of Paris.—*Le Progrès médical* for October 28th gives a biographical sketch of the late Dr. Léon Clément Le Fort, professor of surgery in the Paris Faculty of Medicine, accompanied by a portrait. The death of M. Le Fort took place suddenly during the week preceding the publication of that issue of the journal mentioned. He was born at Lisle in 1829 and took his degree in medicine in 1858. In the following year he served as a medical volunteer in a subordinate capacity in the Italian campaign. In 1861 he was nominated prosecutor to the faculty. He was appointed surgeon to the Hôpital des Enfants-assistés in 1865, to the Midi in 1866, to the Cochin in 1867, to the Lariboisière in 1871, and to the Beaujon in 1872. In 1873 he was made professor of surgery in the Faculty of Medicine. He was a chevalier of the Legion of Honor and a member of many learned societies.

HISTORICAL NOTES ON
THE QUESTION OF THE VALUE OF TRACTION
IN THE TREATMENT OF HIP DISEASE.*

By A. B. JUDSON, M. D.,

ORTHOPÆDIC SURGEON TO
THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

THE treatment of hip disease has greatly changed in the last forty years. It can be still further improved, beyond a doubt, and to prepare for further advance we should keep well in mind the history of the past. As a slight contribution to such history the following summary or outline has been thought worthy of presentation.

The compilation from which the following extracts are taken was made previous to 1883. The reader will therefore not expect to find references to the many and valuable contributions to the literature of the subject which have been made since that date. I regret my inability, for various reasons, to bring these notes up to the present time. Neither can I claim that they are complete for the period which they cover. They are complete only so far as books and papers were readily accessible.

The manuscript compilation above referred to was made in the course of an inquiry as to which of the various opinions concerning traction expressed the correct explanation of its generally recognized good effects. The result of this inquiry—that is, the opinion which seemed to me correct—is noted in its appropriate place.

Incidentally several points of interest came into view. For instance, the word *extension*, used to signify a drawing down or away, has given place to the less ambiguous word traction.† Again, we hear but little of late years of spontaneous dislocation as a feature of hip disease. It was formerly considered an extremely important incident of the late stage, an opinion challenged by Dr. Alden March, who declared that “spontaneous dislocation of the hip (as purely the result of morbid action unaided by superadded violence) seldom or never takes place,” adding that his convictions were “based upon actual observation and personal examination of about forty pathological museums in this country and in Europe.”‡ Dr. George Hayward took the opposite side, saying: “It would require more specimens than would fill forty, or forty thousand, pathological museums to convince me that this [case related] was not a spontaneous dislocation of the femur.”*

The merits of this rather nice question were presently lost in the interesting practical questions which arose when efficient and continuous traction became possible with the introduction of adhesive plaster as a means of grasping the limb. Traction then became useful, not to reduce disloca-

tion, but to relieve pain and promote recovery. And, with the beginning of what may be called the adhesive-plaster era, the effects of muscular contraction and measures for moderating or preventing them became the ruling subjects of observation, experiment, and discussion. In 1860 Dr. Davis published the first description* of the application of adhesive plaster for prehension and traction of the limb in hip disease, and thus excited interest in the subject to such a degree that in the following year the treatment of this affection was discussed in three successive stated meetings of the New York Academy of Medicine by Dr. Batchelder, Dr. Bauer, Dr. Bronson, Dr. Gurdon Buck, Dr. H. G. Davis, Dr. Finnell, Dr. Holcombe, Dr. Krackowizer, Dr. Minor, Dr. Willard Parker, Dr. Post, Dr. Raphael, Dr. Sayre, Dr. A. H. Stevens, Dr. John Watson, and Dr. James R. Wood.† And four years later a not less important discussion on hip disease, in which the new treatment found its advocates and opponents, was carried through many sessions of the Surgical Society of Paris by MM. Blot, Boinet, Bouvier, Broca, Depaul, Dolbeau, Follin, Giralles, Guer-sant, Hervez de Chégoin, Le Fort, Marjolin, Trelat, Vel-peau, and Verneuil.‡

In these discussions and in contemporaneous and subsequent writings on the subject it is evident that muscular contraction was receiving unwonted attention. On the one hand the muscles appeared to threaten the joint, and on the other hand traction appeared to be the stout opponent of the muscles, and the result of the contest was the relief of pain. From these clinical premises, and too hastily in all probability, the conclusion was drawn that muscular action was the chief pathological factor and that traction was the most important therapeutic agent.

Reflex muscular contraction in joint disease had long been recognized. John Hunter, in his lectures delivered in 1786 and 1787, said: “This stiffness of the joint depends on the involuntary contraction of the muscles, and is in consequence of the muscles sympathizing with the joint.”

“Of Muscles losing their Action from Injuries done to Joints, Tendons, and Ligaments.—It is remarkable that an injury done to tendons, ligaments, fasciæ, etc., especially of the strain kind, impair [*sic*] the muscles more than when the muscles themselves are injured, so that these muscles appear to sympathize with those parts of little motion and become wasted and weakened in consequence. I think this arises from sympathy, or a consciousness of the parts being unable to answer to the action of the muscles, and it comes nearest to human reason of anything in the body. If the affection be temporary, as in common inflammation, the muscles do not waste, being conscious that the parts will recover.”*

Reflex contractions were observed in hip disease by Guersant and Maisonneuve, and were considered by them

as important guides to diagnosis.* Traction and counter-traction were applied to prevent their evil effects in the practice of Le Sauvage,† Brodie,‡ Alden March,§ and Gustav Ross.||

But these observations and experiments attracted no particular attention until Dr. Davis made traction by adhesive plaster in the treatment of hip disease. This material had been used in the last century to control muscular action after rupture or division of the tendo Achillis and fracture of the patella,⁴ and Dr. S. D. Gross made traction by adhesive plaster in fractures of the leg in 1830.⁵ But this method of treating fractures was not generally appreciated till Dr. Josiah Crosby advocated it in 1850.⁶ One of his patients described the sensation of traction thus applied in these words: "It feels as if my leg was in the mud, and I was trying to pull it out."⁷ The words were homely, but they heralded in common phrase a happy emancipation from the pain and disappointment which had ever been the lot of patient and surgeon when traction was applied by bandage, fillet, or laced gaiter.

This simple and successful mode of prehension of the limb was first used in the treatment of diseases of the joints by Dr. Henry G. Davis,⁸ an honorary member of our association, who named his treatment the American method**—a name which has sufficient warrant in the fact that the distinguishing feature of the method is the application of traction by the use of adhesive plaster, a device which had its origin in this country.

The immediate and earnest advocacy by Dr. Davis, Dr. Sayre, and Dr. Fayette Taylor of this method of treating hip disease at once opened a new field of clinical observation and experiment, which has been under industrious and ingenious cultivation ever since. A short and very incomplete list of the questions concerning traction, which have been raised and answered in different ways, includes the following: The question of fixation, the question of separating the articular surfaces, the question of moderating the pressure between the articular surfaces by counteracting the muscles, the question of stretching the muscles till they are paralyzed, and the question of keeping them stretched while motion is made in the joint.

presented with the desire to facilitate an agreement among us as to the *modus operandi* of the method with which we have been credited:

Adams, William. On the Treatment of Hip-joint Disease by Extension with Motion, as practiced by the American Surgeons, instead of Long-continued Rest and Immobility. *British Medical Journal*, January 5, 1878, p. 10: "The object of this paper is to direct attention to the recent advances which have been made in the treatment of hip disease by American surgeons. . . . The first principle is that of extension as a means of relieving the most acute pain in joint diseases. . . . The second principle is that of extension combined with motion. . . . The object of extension is not, as generally supposed, to separate articular surfaces, but to overcome reflex muscular contraction and, by relaxing the muscular rigidity, to prevent undue pressure of inflamed surfaces. . . . The English idea has always been rest and immobility to the joint. The American idea, during the last ten years, has been extension with motion—i. e., preserving motion in the joint while the pain is relieved by extension."

Agnew, Dr. Hayes. *The Principles and Practice of Surgery*, 1881, vol. ii, p. 183: "They [walking splints described] are all constructed on very much the same principle and with a view to permit motion in the joint without articular pressure or friction—an impossible task."

Andrews, Edmund. New Instruments for the Treatment of Hip Disease. *Chicago Medical Examiner*, December, 1860. Describes his splint applied to the inner side of the limb, with a sliding rod carrying a crutch head and screw for extension. Adhesive straps are attached to either side of the leg. Page 274: "The screw is then turned up until the padded crutch top rests firmly against the perineum and the desired extension is accomplished. In this way the weight of the patient rests upon the instrument and the instrument upon the ground without impairing the extension." Notes of Surgical Cases. *Chicago Medical Examiner*, June 1861, p. 294: "These [splints to keep up extension] are used in all stages of the disease. In the early months of the attack the extension takes away the pressure of the inflamed head of the femur in the joint and allows it to recover. After an operation it is used to prevent too great shortening while the end of the femur is contracting a ligamentous adhesion to the sides of the pelvis."

The New Splint for Hip Disease. *Chicago Medical Examiner*, August, 1861, p. 445: "Slight motion of the joint when it is firmly extended is of but little consequence."

Improved Methods of Treatment in Joint and Spinal Diseases. *Chicago Medical Examiner*, September, 1863, p. 428: "The local treatment of hip disease in the first or inflammatory stage consists in the application of some suitable instrument by which the weight of the body and the tension of the muscles can be entirely taken off from the joint, so that the inflamed surfaces no longer press and rub against each other." Page 430: "In the use of this instrument [an extension splint applied on the inner side of the limb] the patient is soon conscious of great relief. Even little children discover in a few days that it greatly relieves their pain, and insist on keeping it on."

Report on Surgery to the Illinois State Medical Society. *Chicago Medical Examiner*, October, 1864, p. 558: "A vast proportion of the spinal, hip, and knee diseases are readily cured by any good extending apparatus which draws sufficiently to take off all the pressure and friction of the inflamed parts."

Armand, Jules. De l'extension continue comme traitement de la coxalgie chez enfants. *Thèse de Paris*, 1878, No. 38, p. 29: "Continued extension [by the American splints] separates the articular surfaces, or at least lessens the pressure." Page 69: "We believe that continued extension is an immobilizing agent. The thigh is drawn down in its axis, the muscles are fatigued and overcome and rendered incapable of movement, and the pelvis is restrained from wide motion by the counter-extension."

Barwell, Richard. *A Treatise on Diseases of the Joints*, London, 1861, p. 261: "Under these circumstances [pain and tonic contraction of the muscles increasing] the proper plan of treatment is to fight against the irritation and to counteract the muscular contraction." Page 266: "To counteract such force [muscular contraction pressing one bone on another], I have invented a form of splint." Page 267: "Besides the mere power of straightening a bent joint (only a secondary use of the splint, and not that for which it was invented), the India-rubber spring counteracts that force which presses the bones too violently together, thereby producing the spasm, keeping up the irritation and the caries. I have seen the most violent pains yield gradually to this contractile force; it appears by its unvarying, constant, and unyielding power to tire out the muscles, to overcome their spasm, and to keep the joint surfaces, if not asunder, still not pressing together."

Lectures on the Natural History and Treatment of Hip-joint Disease. *Lancet*, 1862, 1863; October 17, 1863, p. 441: "Perhaps you will tell me that I am arguing in a circle—that having asserted the muscular spasm to be due to inflammation, it is not logical to prove inflammation due to the spasm. True, this is a circle; but it is Nature's own, and not mine."

Diseases of Joints, 2d edition, 1881, p. 464: "To prevent this pressure [produced by muscular contraction], or at least to mitigate its effects, is the object of extension."

Bauer, Louis. Some Observations on Hip-joint Disease and its Rational Treatment. *New York Journal of Medicine*, September, 1853, p. 173: "We possess in permanent extension [traction?] a sovereign remedy for overpowering muscular reflex action, and ultimately restoring the greatly distorted form."

Discussion in the New York Academy of Medicine. *American Medical Times*, May 4, 1861, p. 297: "The new instrument [combining motion with extension] was admirably adapted to control and alleviate progressive hip disease." May 25, 1861, p. 345: "It was not possible for the articular surfaces to be directly separated by an extension so insignificant as that exercised by the splints."

Lectures on Orthopaedic Surgery, New York, 1868, 2d edition, p. 282: "I have derived little or no benefit from extension *per se* in the treatment of progressive joint diseases. Whatever benefit I have derived from it at all is

unquestionably due to its collateral effect upon fixing the affected articulation."

Blandin. M. Maisonneuve (*Annales de la chirurgie française et étrangère*, 1844, pp. 191, 192) says that M. Blandin advocates and practices a combination of extension of the limb with continued traction, saying that it is "a wonderful thing to see how the pain, often extremely severe, of hip disease disappears as if by enchantment."

Bæckel, Eugène. Des effets de la coxalgie infantile sur la croissance ultérieure du membre. *Archives de physiologie*, vol. iii, 1870, p. 558: "Continued extension is also a method of immobilization, and many surgeons still object to the latter on the ground that it produces ankylosis. But it is arthritis, not immobilization, that produces ankylosis."

Des applications de la traction continue au moyen de l'appareil à sparadrap. *Bulletin général de thérapeutique*, vol. lxxxix, 1875, p. 449: "Continued traction by the American method consists in traction of the joint by a suspended weight through the intervention of adhesive plaster applied to the limb." Page 456: "The effect of continued traction in hip disease is first to relieve the pain, then to remove or lessen the pressure of the head of the femur in the acetabulum, and finally to reduce the deformity."

Bradford, Edward H. The Treatment of Hip Disease. *Boston Medical and Surgical Journal*, November 11, 1880, pp. 465, 466: "It would seem, therefore, reasonable to infer [from experiments described in detail] that the relief given by extension in some cases of hip disease is due to the actual separation of the bones involved in the joint, and that this more frequently is not the fact in the early stages of the disease is probable, considering the anatomy of the joint. In these cases, however, the muscular force which in disease draws the femur upward, crowding the head against the acetabulum or forcing it above the normal position of the latter, is counteracted by thorough extension. It is to this, probably, that the relief obtained by extension in the majority of cases is due. This relief is so marked that there can be no doubt of its efficacy as a means of treatment. It is also true that extension, provided the pelvis is steadied, can be made to give efficient fixation, but it is manifest, from cases which are frequently met with, that simple extension without any attempt to secure the pelvis gives great and immediate relief." Refers to experiments of Morosoff, König, Paschen, Schultze, Reyher, and Ranke, made to determine the effect of extension on separation of the head from the acetabulum and on the degree of hydraulic intra-articular pressure.

Brodie, Benjamin. *Pathological and Surgical Observations on the Diseases of the Joints* (third London edition, 1834), Washington, 1834, p. 55: "At a later period when, in consequence of the extensive destruction of the articulation, the muscles begin to cause a shortening or retraction of the limb, I have found great advantage to arise from the constant application of a moderate extending force, operating in such a manner as to counteract the action of the muscles. For this purpose an upright piece of wood may be fixed to the foot of the bedstead opposite the diseased limb, having a pulley at the upper part. A bandage may

be placed round the thigh above the condyles with a cord attached to it, passing over a pulley, and supporting a small weight at its other extremity."

Clinical Lectures on Surgery—Philadelphia edition, 1846, p. 297—describes the same apparatus: "In this upright piece of wood there is a pulley, which pulley is just in line with the thigh bone. . . . A few ounces of lead or some copper penny pieces put into a basket are sufficient in the case of a child. . . . The patient suffers because the head or neck of the femur is leaving its own place and getting into new parts which are not intended to have the rough bone in contact with them. . . . It is astonishing what comfort I have known this to give the patient in some instances."

Diseases of the Joints—fifth edition, London, 1850, p. 139—describes the same apparatus, a leather strap being substituted for the bandage above the condyles of the femur and "the pelvis being at the same time fixed by a strap to the middle or upper end of the bedstead." Page 140: "This in some instances seemed to relieve the pain, and I am inclined to think it was useful otherwise by counteracting the muscles, which tended to draw the limb upward. However, it almost always happened that something occurred to prevent the experiment being fully and fairly tried; and all that I can venture to say respecting it is that it may be worth while, in certain cases, to give this mode of treatment a further trial."*

Busch. Armand, on pages 74 and 75 of his thesis, states that Busch affirms the good effect of continued extension on the course of the disease, but believes it to be the result of an increase of hydraulic pressure in the capsule, in opposition to which Armand cites the experiments of König and his own.

Cooper, E. S. Editorial, *San Francisco Medical Press*, July, 1861, p. 145: "Often have patients slept better the first night after its application [referring to his tin splint for extension] than they had done for months previously."

Davis, Henry G. Deformities and their Remedy. *American Medical Monthly*, March, 1856, p. 212: "These artificial muscles answer another important part in wearying out the contracted muscles by their constant action night and day, thus tending to elongate them." May, 1856, p. 329: "This same principle of treatment—viz., the separating of the diseased surfaces and removing from them all irritation from pressure—is equally applicable to disease of the hip joint." Page 330: "This [rubber used as an extending power] will act steadily and gradually without any violence and with very little suffering in comparison with permanent fixtures. When contracted muscle is to be overcome, it stealthily wearies it until it silently comes off conqueror."

A Case of Pott's Disease, with Remarks. *American Medical Monthly*, November, 1859, p. 361: "In morbus coxarius we separate the diseased head of the femur from the

acetabulum, thus leaving the parts in a condition to recover so far as pressure might have interfered. By this means we also get in both instances [Pott's disease and hip disease] passive motion without friction."

On the Effect of Pressure upon Ulcerated Vertebrae and in Morbus Coxarius. *New York Journal of Medicine*, November, 1859, p. 418: "Extension was made upon the limb, and after the muscles had become wearied so as to allow the head of the bone to come down upon the inferior portion of the acetabulum, the pain was relieved." Page 420: "I can but consider it highly beneficial to keep up motion of the joint, yet not allow friction upon the diseased surfaces."

On the Mechanical Means adopted in the Treatment of Morbus Coxarius. *American Medical Monthly*, April, 1860, pp. 263, 264: "The extension is first made at that angle with the body that I find the limb; as the tenderness of the joint subsides, the body should be gradually lowered until it is brought in a line with the limb; when this is effected, the splint can be applied and the patient put upon crutches and permitted to exercise." Page 267: "It puts the diseased parts in the best position for their restoration with a perfect joint, as it relieves the pressure upon the head of the bone, while at the same time it admits of motion, which increases the recuperative energy of the parts, inasmuch as it increases vitality."

On the Advantages of Elastic Extension in Morbus Coxarius. *American Medical Times*, Sept. 1, 1860, p. 149: "When I speak of extension I do not apply the term to confining the limb in a given position, but to the process by which the soft parts are kept continuously upon the stretch, whether by means of a weight and pulley or some elastic material, the result of which process upon the muscular fiber is to weary it and put it at rest."

On the Pathological Basis of the Treatment of Joint Diseases. *American Medical Monthly*, November, 1862, p. 323: "If handled a little roughly all the muscles will be upon their guard." Page 336: "When extension is made by an elastic material the muscular fiber becomes wearied, the nervous influence is expended, and the bones come down until the extending power is exerted entirely upon the unyielding tissues. . . . An unremitting draft is kept up upon the muscles, and yet the limb is not fixed but that the muscles may contract and thereby exhaust their nervous influence and ultimately rest like any muscle wearied from exercise."

The American Method of treating Joint Diseases and Deformities. *Transactions of the American Medical Association*, 1863, p. 150: "Pressure, mostly owing to muscular contraction, is the most active agent of destruction in the morbid process. . . . The essential parts of the apparatus are simply means of exerting an elastic, continually extending force on one side and a resisting counter-extending one on the other." Pages 154–156: "The joint becomes in a manner fixed . . . as a remedial measure. . . . It undoubtedly is to protect the surfaces of the joint (that come in contact in the natural movements of the limbs) when diseased from friction. . . . So far as this object can be accomplished by the muscles holding the joint motionless

* Sir Benjamin was very familiar with Scott's dressing of those days, which consisted of adhesive plaster applied so abundantly as to obstruct the motion of the hip. It would have been a happy thought to use the same material with his weight and pulley instead of the bandages and leather strap.

they so act. Now, in effecting this immobility, are the muscles of the diseased joint relaxed, and therefore at rest? Or are they in a semi-contracted state, and thus fix the joints by acting equally upon every side of it? . . . If it is true that the diseased joint is held in a fixed position by a certain rigidity of the muscles passing to or beyond it, an amount of pressure corresponding to the contractile force of the muscles as then exerted must be produced upon the articulating surfaces of the joint, . . . producing absorption, when not sufficient entirely to arrest the nutrition of the parts, and when going beyond this point death, with exfoliation of the parts pressed upon."

Conservative Surgery, New York, 1867, pp. 85, 86:

"After the lapse of an indefinite period from the receipt of severe injury to a joint the muscles acting upon it sometimes pass into a state of fixed contraction, or may start into spasmodic action upon any effort being made to move the joint either voluntarily or by the attendant. . . . This action of the muscles is not dependent upon any disease of their fibers or their nerves, but is simply a contraction for the purpose of preventing, instinctively as it were, motion in parts where motion is productive of pain. This constant contraction of muscles passing over a joint, thereby guarding with increased vigilance against motion, when all movements of the joint give pain, is the efficient cause of the destruction of the parts pressed upon or against each other, and should always be counteracted." Page 206: "When disease about a joint renders the movements of that joint painful, . . . the joint is always liable to be destroyed by uninterrupted pressure effected through the contraction of the muscles passing over it. They do this by preventing the parts pressed upon from receiving nourishment, in the same way as a bed sore is produced." Pages 209, 210: "The treatment of simple synovitis in its earlier stages by extension is as imperatively demanded as at any later period, and relieves the pain as effectually. . . . Continued elastic extension is applicable not only to synovitis, but to all other diseases within the capsule; and not only these, but when parts about or in the vicinity of a joint are so painful as to compel the individual to hold the joint motionless, extension should be applied, for the reason that the pressure exerted by the muscles in holding the joint motionless will strangle the nutrient vessels of the parts held in contact." Pages 212, 213: "In diseases of the joints we were the first to point out, as an always-present factor in the destruction, the existence of unremitting pressure as effected by contraction of muscles passing over the joints causing constant forcible opposition of the surfaces within the joint. . . . When this fact was fully established in our mind we were led to seek the best way of counteracting the contraction of the muscles, and soon came to the conclusion that a constantly acting force, however moderate, must eventually weary muscles by giving them no respite." Page 214: "The first splint, as well as all my modifications, admits of free motion at the diseased joint, but rigidly excludes all friction of the diseased surfaces within the joint upon each other. This we consider the essential element in the treatment of the disease under consideration—viz., motion without friction."

Gibney, V. P. *The Hip and its Diseases*, New York, 1884, p. 324: "By far the surest method [of relieving pain] is fixation and traction. The weight and pulley sometimes act like a charm. The spasm is overcome, the limb is supported, and the child falls asleep without fear." Page 358: "The one practical idea, however, to which all these splints tend is immobilization or fixation, with the associated idea of motion if desirable." Pages 359, 360: Points that seem to be settled: "(1) Traction does not produce any appreciable separation of the head of the bone from the acetabulum. (2) It does induce fixation and prevents concussion. (3) It relaxes muscles by overcoming reflex spasm. (4) Fixation is considered of far more value than pure extension. (5) Traction to be efficacious must be in the line of the deformity."

Hennequin. Quelques considérations sur l'extension continue et les douleurs dans la coxalgie. *Archives générales de médecine*, December, 1868, p. 79: "Continued extension, having overcome muscular power, separates the articular surfaces and does away with pressure and pain." Page 80: Recognizes the vicious circle in which pain increases muscular action, which in turn produces more pain. Suggests the theory that the contracting muscles keep the femoral head turned in such a way that the less sensitive portions of its surface receive the pressure. Page 176: "The object of continued extension is to paralyze the action of the muscles." Pages 186, 187: A case of eighteen months' duration in a girl of eighteen years with apparent shortening of ten centimetres treated by continued extension. "Twenty-four hours had not passed before the pain disappeared, the pelvis descended laterally around the lumbar column, the swelling subsided, and a cheerful confidence succeeded depression."

Hildreth. Discussion in the Boston Society for Medical Observation. *Boston Medical and Surgical Journal*, April 26, 1877, p. 506: "Dr. Hildreth thought that not so much extension was required as rest; extension sufficient only to overcome the muscular contraction."

Holmes, Timothy. *Surgical Treatment of the Diseases of Infancy and Childhood*, London, second edition, 1869, p. 444: "The early symptoms of hip disease are in a great measure muscular, and can only be treated successfully by measures directed to the relief of muscular contraction—i. e., by mechanical extension." Page 447: "The first indication of treatment is to place the parts at perfect rest under the influence of sufficient extension to avoid exacerbations induced by muscular spasm." Page 448: "I have found nothing answer so well as the old plan of suspending a weight to the foot sufficient to overbalance the tension of the muscles. . . . The spasmodic pains will subside and the child, freed from the irritation and the loss of sleep which they occasion, will rapidly recover the aspect and appetite of health. . . . The most convincing experiment and one which I have frequently repeated is, after the starting pains have subsided (which they do usually on the second or third day from the application of the weight), to leave it off, when they will almost infallibly recur on the second succeeding night, again to disappear on renewal of the treatment."

Hugman, William C. *On Hip-joint Disease*, London, second edition, 1866. Pages 35-39 contain reference to the Fifth Report of the Hamburg Hospital, where treatment was "in the latter stages by keeping up a gradual extension, so as to overcome the spasmodic action of the extensor muscles, which, according to the opinion of Dr. Fricke and Dr. Taudtmann, when dislocation had taken place, not only tends to increase the deformity by further shortening the limb, but also adds to the inflammatory condition of the part by friction of the head of the thigh bone upon the dorsum of the ilium."

Hutchison, Joseph C. *Contributions to Orthopaedic Surgery*, New York, 1880, pp. 8, 9: "The object of extension is: (1) To correct the malposition of the limb. . . . By means of extension we also (2) overcome the spasm and contraction of the muscles which, by reflex contraction, press together the inflamed articular surfaces, and constitute the chief cause of pain in joint inflammation; but I do not think it possible by any amount of extension that can be applied to separate the inflamed and swollen interior surfaces of the joint so as to relieve them from pressure and the consequent pain. What we do accomplish by extension is the relief of spasm and of muscular shortening; and to quiet the muscles is an important therapeutic axiom . . . motion without friction, a condition which . . . seems to me to be a mechanical absurdity. We might with equal propriety speak of sound without vibration of the air." Pages 18, 19: "To obtain extension of the limb no apparatus is required. Extension is made by the weight of the suspended limb [the patient being provided with crutches and a high sole on the well foot], which is equal to a fifth of the whole weight of the body and is greater than the weight usually employed for extension. This is quite sufficient to subdue the spasm of the muscles which crowd the head of the bone into the inflamed acetabulum and is the chief cause of the pain which the patient experiences. . . . The extension not only relieves pain, but it corrects the malposition." Page 40: "The spasmodic contraction of the peri-articular muscles is overcome by the gentle, persuasive, and painless (physiological) extension made by the weight of the limb." Pages 19, 20: "This plan of treatment should be adopted . . . except in the comparatively rare form . . . attended with great constitutional disturbance and excruciating pain. . . . Until after the acute symptoms have subsided such cases should be treated in bed with the long splint and the weight and pulley."

Discussion in the New York Academy of Medicine, *Medical Record*, May 1, 1880, p. 492: "He believed it to be impossible to separate the head of the bone from the acetabulum by any mechanical appliance, and all an apparatus could do was to prevent the head of the bone from jamming up into the acetabulum, and thus prevent pain."

Hyde, J. N. An Adaptation of the Plaster Jacket to the Splints for the Hip. *American Journal of the Medical Sciences*, July, 1877, p. 124: "It will be seen from the preceding description that the hip splint, as thus modified [combination of plaster-of-Paris jacket and short traction splint], provides for extension and counter-extension, with free mobility and without perineal pressure."

Judson, A. B. Considerations respecting the Mechanical Treatment of Hip Disease, with Especial Reference to the Value of Traction. *St. Louis Courier of Medicine*, May, 1881, p. 370: "The advantages derived from the traction exerted by the hip splint are due solely to the fact that it secures fixation." Page 371: "It is not believed that the hip splint secures absolute immobility, but fixation or a reasonable degree of immobility."

Some Practical Inferences from the Pathology of Hip Disease. *New York Medical Journal*, July, 1882, pp. 9, 10: "In these cases [early stage] the articular surfaces directly exposed to pressure are free from erosion or ulceration, while the underlying spongy tissue of the bone is deeply implicated, and yet reflex muscular contraction is one of the earliest recognizable symptoms. So far as the incipency of the disease is concerned, the recorded facts of pathology fail to sustain the importance of muscular action." Pages 10-15: In the middle stage ulcerations first appear on the neck and not on the articular surface, and when the articular surface is marred its lesions are less severe than those of the underlying tissue—facts which show that the morbid action proceeds from within outward, from the interior of the bone toward its surface; whereas, if the muscular contraction were an important factor the reverse would be true. When the evidences of pressure are found they are seen in the altered shape of the head and neck of the femur, and are as readily referable to the pressure and concussion incident to standing and walking as to the pressure resulting from muscular contraction. Page 15: "In this [the late] stage the signs of disease are never limited to the parts directly exposed to pressure, for all the surfaces of the upper extremity of the femur and sometimes a portion of the shaft are thoroughly diseased. If the action of the muscles is productive of mischief in this stage, the unremitting and firm pressure which is thought to accompany reflex muscular action ought to produce effects much graver than those which are found." Page 16: "If the femur were in fact propelled by such a force, instead of the recession of the upper edge of the acetabulum and the occasional perforation of its floor we should have in every case, and soon after the accession of the disease, an abrupt invasion of the pelvic cavity by the decapitated femur."

What is the Rationale of Traction and Counter-traction in the Treatment of Hip Disease? *Medical Record*, May 12, 1883, p. 511: "There are great mechanical difficulties in the way of the practical application of this idea [traction with motion]. If traction and counter-traction are applied in the line of the thigh and trunk, it is difficult to conceive that the same amount of force can be maintained through all the variations of flexion, extension, adduction, abduction. . . . The idea is that traction and counter-traction are curative because they deprive the muscles of their contractility. Muscular fiber may lose its contractility from rupture or degeneration, but that it surrenders this high endowment to the application of traction is, to say the least, extremely questionable. If an elastic force be used, the muscles to which it is applied would probably increase in size and vigor from the exercise."

The Fixative Power of Traction in the Treatment of Hip Disease. *Medical Record*, July 7, 1883, p. 2: "Take two rods of iron and form an eye in the end of each by bending its extremity into a small circle. When the rods are joined by these eyes they will together resemble two links detached from a surveyor's chain, and there will be wide and free mobility at the joint. Then tie the free end of one link to a staple and apply traction, by means of a weight and pulley, to the free end of the other. It is seen at once that the mobility which existed at the joint between the links is absent so long as the traction continues. . . . Or subject the two links to traction in a hip splint, tying the free end of one to the perineal straps and that of the other to the leather straps which lead to the foot piece. The result of applying traction by the rack and pinion is fixation of a remarkably stable and indestructible kind." Page 4: "The fixation which this apparatus secures is of a peculiar quality. It may be compared to the condition found in some forms of paralysis, when a joint is said to resemble a leaden pipe, which may be bent with suitable force, but retains with sufficient firmness whatever position it may be placed in. This fractional degree of fixation is attended with sufficient arrest of motion to allay inflammation, encourage the reparative process, and afford relief from pain; and yet it is not so inflexible as to prevent the gradual correction of deformity in obedience to the unconscious efforts of the patient to place the limb in its most useful position, which is that of slight flexion with neither adduction nor abduction.

Knight, James. *Orthopædia*, New York, 1874, p. 263: "Nothing is more fallacious than to expect a cure to be made by a continued extension of the limb, as that of the weight and pulley, which continues to extend . . . to the impairment of the tone of the muscles. In our experience it is only palliative to pain, and not curative, but actually injurious as a treatment."

Le Fort. Discussion in the Surgical Society of Paris. *Bulletin Société de chirurgie*, March 8, 1865, p. 77: An indication urged by American surgeons is continued extension, "not to prevent spontaneous dislocation, but to promote cure of the disease and especially to relieve the pain often so severe in the early stages." Le Fort's extension apparatus described by Philippeaux (*Traité de thérapeutique de la coxalgie*, Paris, 1867, pp. 418, 419) is designed to gradually reduce flexion, to diminish pressure of the head in the acetabulum, and to permit locomotion and motion in the joint.

Le Sauvage. Mémoire théorique et pratique sur les luxations dites spontanées ou consécutives, et en particulier sur celle du fémur. *Archives générales*, November, 1835, p. 280: "I believe that the use of the bandage for continued extension is not only to lengthen the limb, which is not necessary in every case, but also to prevent motion and pressure caused by muscular contraction."

Liston, Robert. Lectures on Diseases of the Bones and the Joints. *Lancet*, November 25, 1843, pp. 237, 238: "All this [the use of a weight and pulley] may amuse the patient's mind, perhaps, but I do not think any good can come of it further than preventing motion."

Macnamara, C. *Lectures on Diseases of Bones and Joints*, London, second edition, 1881, p. 425: "There can be no question that spasm of the muscles in cases of this kind may be overcome by extension effected through a weight and pulley, a means of treatment which can not be too highly recommended."

March, Alden. On Coxalgia, or Hip Disease. *Trans. of the Am. Med. Assoc.*, 1853, p. 499: "It is proposed now to show how extension and counter-extension . . . can be explained on pathological principles. . . . By the pressure of the muscles that act on the head of the bone and acetabulum, in addition to ulcerative absorption, we get progressive absorption, and hence the great destruction of the osseous parts of the joint. . . . Extension and counter-extension are used with a view to prevent undue pressure on the delicate and tender surfaces of the diseased bones."

Markoe, Thomas M. *A Treatise on Diseases of the Bones*, New York, 1872, p. 114: "There is a mode [weight and pulley] of securing rest to the limb . . . which is attended with the very great advantage of relieving the pressure of the joint surfaces against one another, produced by the tonic contraction of the muscles surrounding the joint."

Marsh, Howard. On the Prejudicial Effect of Inter-articular Pressure in Joint Disease; and the Application of Continuous Extension, by Means of a Weight and Pulley, as a Remedy for this Condition. *St. Bartholomew's Hospital Report*, 1866, p. 149: "When the child had become free from pain, which was usually the case in from three to eight days, I went during the night, while he was asleep, and raised the weight and lodged it in the bottom of the bed, thus setting the muscles free from restraint and giving them liberty to contract. In a very few hours many of the children so treated became restless in their sleep, and presently awoke with the old pain, and screaming. . . . The influence of such pressure as that which muscular action produces on the surfaces of a diseased joint is in the highest degree prejudicial." Page 150: "Seeing how grave an influence is excited on the course of joint disease by the pressure and bruising which the articular surfaces inflict upon each other, both during any movement of the limb and during muscular action, it is obviously of importance in treatment (1) to keep the surfaces at all times from contact, and (2) to control the muscles." Page 151: "The necessity of providing artificially for the relief from pressure in disease is obvious when it is remembered that in the spontaneous course of events not only is the pressure constant, but also that it is greatly increased in its amount by abnormal muscular action. Extension by means of a weight is well adapted for supplying this need. The second indication in the management of joint disease to which I have referred is to control irregular muscular action. As this abnormal action is due, as we learn from Mr. Hilton, to the inflamed condition of the joint, it may be expected to subside when the inflammation passes off. Until this is the case, however, it will be found that it is perfectly controlled by continuous extension. By this force the muscles are tired out, and are soon made to capitulate."

Lectures on the Diagnosis and Treatment of Hip Disease in Children. *British Med. Jour.*, July 28, 1877, p. 98: "As the muscles and other rigid structures yield, the limb will subside into its natural position until it is in full extension and parallel with its fellow. As this change goes on, you must gradually shift the pulley so that it is kept still in the line of the long axis of the femur." Page 99: "The greatest amount to which the surface of the head of the femur can be separated from that of the acetabulum can not be more than about the tenth of an inch. And it is very difficult to preserve efficient extension and counter-extension within this range, for the parts can not be acted upon as if they were parallel metal plates to be adjusted by a screw; they must be controlled through the agency of perineal bands and strapping fixed upon the skin, and all these are apt to give when they are subjected to constant traction; and, if they yield, though it be but slightly, they soon, in the aggregate, lose this tenth of an inch of extension which they should maintain, and then the articular surfaces come again into firm contact. Besides, I may refer to what has seemed another difficulty. Both Dr. Sayre and Dr. Taylor allow their patients to move the thigh upon the trunk by bringing it toward flexion, and it has always appeared to me that if the perineal band be adjusted, according to their direction, when the limb is extended, it will become loose when the limb is flexed."

Maylard, A. Ernest. The Double Splint in Affections of the Hip. *Glasgow Med. Journal*, March, 1882, p. 162: "To obtain what is absolutely necessary for joint repair—perfect rest—movement must be checked, muscular action counteracted, and, still further, any pressure of the inflamed surfaces upon each other prevented."

Monod, Charles. De l'extension continue dans le traitement des arthrites. *Arch. gén.*, June, 1878, pp. 723-725: "Recall the painful contraction, the muscular rigidity of arthritis, the *vigilance musculaire*, protecting the joint from inadvertent disturbance, but entailing deformity and destruction. Evidently continued extension, especially if applied in the early stages, acts by combating the excited muscles. Challenging them to the contest, it deprives them of their power, and in this lies the great advantage of this method. . . . Traction, really continuous, must triumph over muscular resistance. If the traction is permanent and strong enough the muscle will, after resisting for a time, finally yield and fall into relaxation. . . . We recall these facts because those who are using this method do not seem to view them aright. Overlooking the real object and seeking to separate the articular surfaces, they are absorbed in increasing the amount of traction, instead of making it really continuous."

Parker, Willard. Discussion in the New York Academy of Medicine. *Am. Med. Times*, May 11, 1861, p. 311: "The treatment of inflammation in the early stage is rest. We get our extension and counter-extension by the application of this splint, and thereby we accomplish everything in the joint. Our patient gets the air, but that joint is still at rest."

Philipeaux, R. *Traité de thérapeutique de la coxalgie*, Paris, 1867, p. 261: "The so-called American method is

the application of continued extension to arrest the progress of acute disease and to dissipate the severe pain so common in the early stage." Page 262: "They apply continued extension to remove all pressure on the articular surface by the weight and pulley at night and special apparatus in the daytime. This practice leads to the neglect of the great principle of immobilization without which nothing can be done." Page 284: "Starting with the mistaken idea that the pain is due to pressure on the articular surfaces and that the shortening is due to absorption of cartilage and deepening of the acetabulum, they apply continued extension to prevent pressure and avert deformity." Page 285: "After deformity is reduced immobility may be assured by continued extension in the absence of proper immobilizing apparatus."

Roberts, M. J. Elastic Extension and Articular Motion as Therapeutic Agents in Chronic Joint Disease. *The Medical Gazette* (New York), Feb. 18, 1882, p. 74: "He believed that it was necessary, in order to preserve the integrity of the joint and the part below it, to keep up a certain amount of motion. . . . If motion without friction was to be obtained, the splint must keep up extension with no articular pressure, and allow for the lateral deviation. What was wanted was an instrument that would automatically lengthen as the limb shortened in flexion. Such an instrument he had devised."

The Hip and its Diseases. By V. P. Gibney, New York, 1884, p. 377: Dr. Roberts describes portions of his splint as "constructed with special reference to exerting continuous elastic linear traction [by India rubber] upon the thigh." Page 379: "By continuously exerting elastic traction, it is further claimed, articular motion becomes possible without interarticular pressure or friction."

The Fundamental Principles of Mechanio-therapy in Hip Disease. *New York Medical Journal*, March 15, 1884, p. 294: "The combined use of efficient resilient support, firm tensile circumferential compression, and elastic linear traction, renders the patient more comfortable and more quickly subdues reflex spasm than the independent use of any one or two of these measures; and during the continuance of their conjoint use, articular motion can be made without the slightest discomfort to the patient." May 3, 1884, p. 490: Maintains "the feasibility of permitting articular motion at the hip, under the restrictions of efficient resilient support, firm tensile circumferential compression, and elastic linear traction."

Ross, Gustav. Ueber ein neues Behandlungsprincip der Gelenkkrankheiten. *Deutsche Klinik*, March 4, 1854, pp. 96-99: Deformity is caused by reflex muscular action. Refers to his statement made in Blandin's clinic, Paris, 1845, that myotomy of biceps in the case of a diseased knee would have lessened caries because the pressure from muscles would have been lessened. In hip disease muscular action prolongs inflammation, and treatment should consist in preventing the contraction of the whole muscular mass around the joint. Treats all cases of joint disease by extension by weights and pulleys. The pain lessens astonishingly.

Sayre, L. A. *American Medical Monthly*, April 1860, p. 298: "When left to itself, the rest which is so essential

to the joint is procured by the firm muscular contraction which prevents the motion in the joint, and is so perfect as in many instances to assume the appearance of genuine bony ankylosis. But this constant muscular contraction exhausts the nervous system and induces hectic fever; gives the child nocturnal spasms of intense agony; prevents nutrition of the limb, which results in atrophy. We therefore resort to artificial means to produce this rest. . . . The great difficulty to be overcome in securing entire rest of the joint is the danger of producing bony ankylosis, resulting from the general inflammation of the surrounding structures, and sometimes great stiffness and partial ankylosis of the well joints. On the other hand, if we remove the instrument and commence passive motion, without keeping up extension, there is danger of reproducing the inflammation. I have therefore come to the conclusion that perfect rest, however essential it may be to an inflamed synovial membrane, is not only unnecessary to the ligaments (which in the earlier stages were not involved in the inflammation), but was positively physiologically wrong. As the eye needs the healthy stimulus of light, so does the ligament need the stimulus of motion. If, then, we can give motion to the ligaments of a joint, while at the same time we prevent muscular contraction, so as to remove pressure from the synovial membrane, we shall accomplish our object." Page 300: "The India rubber, by the permanency of its contraction, will overcome the muscular rigidity."

Report on Morbus Coxarius, or Hip Disease. *Trans. Am. Med. Assoc.*, 1860, p. 475: "If the effusion be excessive, or the inflammation acute, you will have an apparent ankylosis, caused by muscular contraction, which is an involuntary act, produced by reflex action of the inflamed or irritated nerves, and is done for the purpose of keeping the joint perfectly still. It affords the natural indication for the surgeon, by imitating this action, to accomplish the same result of perfect rest to the inflamed synovial membrane. This we may do in a much more effectual manner, for at the same time we succeed in relieving the other parts from a pressure which, if long continued, must cause, in the absorption of the cartilage and bone, the destruction of the joint. Motion, when not accompanied by extension, is much more painful than rest, even if accompanied by the pressure caused by the muscular contraction. Hence the patient, naturally choosing the least of two evils, obtains rest of the part by muscular rigidity, even at the expense of the absorption arising from the pressure."

Objections to the Treatment of Morbus Coxarius in its Advanced Stages by Extension, unless preceded by Tenotomy. *American Medical Times*, May 9, 1863, p. 219: "The object of extension in the inflammation of all joints is to relieve pressure from the inflamed synovial membrane and cartilage."

On the Mechanical Treatment of Chronic Inflammation of the Joints of the Lower Extremities. *Transactions of the American Medical Association*, 1865, p. 379: "Chronic inflammation of any joint produces reflex contractions, causing deformity and severer pain by increasing pressure at the diseased surfaces, thus making extension and counter-extension a necessary part of the treatment."

Introductory Lecture, New York, 1868, p. 11: "I have been enabled to test the correctness of the now established principle of extending a contracted muscle by the constant application of an elastic force, moderately but persistently applied."

Clinical Lecture on Fibrous Ankylosis. *Medical Record*, Sept. 1, 1874, p. 449: "Extraordinary results can be obtained in the way of overcoming muscular rigidity by the application of a constant unremitting force. Under circumstances favoring the application of constant unremitting elastic force equally as favorable results can be obtained by paralyzing muscular power, thus overcoming deformities produced by it."

On Ankylosis. *Transactions of the New York Academy of Medicine*, 1874, p. 27: "This contraction [produced by reflex irritation] not only aggravates the disease by causing undue pressure on the parts inflamed, but also distorts the limb in accordance with the action of the most powerful muscles involved, and the distortion can only be prevented by the proper application of an extending and counter-extending force during the treatment of the disease."

Lectures on Orthopaedic Surgery, New York, 1876, p. 244: "This pain, moreover, is self-perpetuating, for the irritation of the diseased joints causes the muscular contractions, and these in turn aggravate the inflammation." Pages 273, 274: "The most important of all the means to be employed [first stage], and the one upon which all prospect of success depends, is rest of the joint and perfect freedom from pressure of the inflamed articular surfaces." Page 275: "Extension is employed [second stage] for the purpose of counteracting the morbid contraction of the muscles, and to relieve the pressure upon the articular surfaces of the joint, and is persisted in until the more prominent inflammatory symptoms have subsided." Page 278: "The object of such appliances is merely to [third stage] relieve the joint from pressure by permanently extending the morbidly contracted muscles and at the same time securing its perfect mobility."

Discussion in the Surgical Section of the British Medical Association. *British Medical Journal*, Aug. 30, 1879, p. 317: "The first point to be attended to is the employment of extension and counter-extension carefully regulated so as to readily relieve the parts from pressure, as indicated by the comfort of the patient. The next great element is rest, as complete and perfect as can be given to the parts." Page 319: "The first principle was rest, as absolute and complete as it could be made, for the individual joint involved in the disease; and the next thing was to prevent the muscular contraction that would always take place whenever there was inflammation. There should be extension of the joint, just such as would prevent pressure and no more; otherwise destructive changes would go on."

Discussion in the Surgical Section of the New York Academy of Medicine. *Medical Record*, Dec. 6, 1879, p. 544: "Constant muscular contraction kept up constant pressure of the diseased surfaces one upon the other, absorption occurred, and where it had extended sufficiently far, the acetabulum was perforated and the head, or rather

the upper extremity of the femur, rode through it. It was to overcome the constant and persistent action on the part of the muscles that some mechanical apparatus was employed which relieved them, and at the same time simply kept the diseased surfaces from coming in contact with each other. . . . By fulfilling these conditions [by extension and counter-extension] the exciting cause of the muscular contractions was removed, and with its removal went the tendency to reflex muscular movements, and at the same time more or less motion in the joint was obtained."

A Clinical Lecture. *Medical Bulletin* (Philadelphia), January, 1882, p. 4: "Where slight extension is made, the movements of the joint can also be made and thus permit of recovery without ankylosis."

Discussion in the New York Academy of Medicine. *Medical Record*, May 1, 1880, p. 492: "Give the parts involved in the disease absolute rest and freedom from pressure without materially interfering with the mobility of the joint. Extension in such a manner as to permit motion should be the object sought for in any mechanical appliance, except in cases in which the inflammation is so violent that absolute rest is required for a time."

Schede. Armand, on page 42 of his thesis gives a case from Schede of a girl of fourteen years who had suffered the acute pain of hip disease for four weeks. For the six days before treatment the temperature was between 101°-1° and 100°-8° in the morning and between 102°-6° and 103°-1° in the evening. Traction was applied, and after a night of sleep, the first in a long time, the thermometer recorded—

The first morning, 99°-5°; evening, 102°-9°.

The second " 100°-4°; " 101°-1°.

The third " 99°; " 100°.

From that time the temperature was normal.

Shaffer, Newton M. On Reflex Muscular Contraction and Atrophy in Joint Disease, with Remarks on Mechanical Extension. *Archives of Clinical Surgery*, June 15, 1877, p. 82: "The primary contraction that occurs in joint disease is reflex. Clinical experience proves that whatever relieves joint pressure and arrests motion will modify the contraction, and that whatever increases joint pressure aggravates the inflammation and intensifies the contraction. The primary indications are therefore to relieve joint pressure and to arrest motion. These can both be accomplished by a properly adjusted extension apparatus. . . . The extension is then exerted, so far as the conformation of the hip joint will permit, directly upon the joint, and the contracted muscles yield as the cause of the contraction is modified."

A Review. *Archives of Medicine*, October, 1880, pp. 198, 199: "When traction exists, the patient has the advantage of that peculiar and perfect immobility which the extension of the long hip splint affords. . . . We made an experiment several years ago which demonstrated beyond a doubt that the Taylor-Sayre instrument produces almost complete fixation in a healthy hip joint. The experiment, in brief, was the application of a hip splint to the right lower extremity of a child, whose left hip was ankylosed from former disease. After the application of the splint to the healthy limb the patient could not walk a step. All motion at the left hip being lost, the boy, with extension, was

unable to bring the flexible vertebral column to his aid. When the knee-cap was loosened and flexion of the thigh was permitted, the patient walked very awkwardly for a step or two."

Stillman, Charles F. Extension and a New Method for its Production. *Med. Record*, Dec. 4, 1880, pp. 620, 621: "The contractile force of the muscles is involuntarily excited to press the opposing articular surfaces still closer together. As a result of the increased irritation, we have . . . injury to the articular surface, and, finally, implication of surrounding tissues. Therefore, in order to overcome this primary irritation of the joint, we must overcome the contractility of the muscles governing the joint."

Tarbell, G. G. A Review. *Boston Med. and Surg. Jour.*, Aug. 31, 1876, p. 263: "The patient is not to be confined, as formerly, to bed, but is to be furnished with such mechanical aid [portative traction splint] as will prevent motion of the joint and slightly separate its inflamed surfaces. . . . Motion at the hip joint [is] the very thing which, in the acute inflammatory condition of the joint, is acknowledged to be harmful, and to prevent which is the sole object of the apparatus."

Taylor, C. Fayette. Improved Counter-extension Splint for Morbus Coxarius. *Am. Med. Times*, July 20, 1861, p. 38: "The movement of every joint of the limb is most perfectly secured, that at the hip especially not being in the least interfered with by the counter-extension force."

Some Considerations in regard to Hip-joint Disease. *Med. Record*, Sept. 1, 1867, p. 290: "I do not believe it [the drawing out of the head of the bone] occurs or ought to occur, nor do I believe it would be anything but harmful if it did occur. The sole object of counter-extension is to destroy the tonicity of the muscles about the hip joint. This destruction of tonicity gives relief and motion. . . . And this should be our aim, and until we have accomplished it we have not realized the benefit of counter-extension treatment at all. If a splint or weight be applied, it may assist in keeping the limb steady and quiet, and in that way the patient may improve; but the improvement is due to the confinement and protection from motion, rather than to extension and motion, which latter are the two sources of benefit when counter-extension is efficient. I repeat, the muscular tonicity must be temporarily destroyed. The counter-extension must be carried to that point. And we have a certain guide as to the amount of force to be used and the extent to which it is to be carried. When we have destroyed tonicity, our chief labor is done. . . . If contractions accompany or follow the disease, we may be sure that our counter-extension has been inefficient, and therefore worthless as such, and that the improvement, if any, is due to the quiet fixation of the joint, which the splint has been a convenient means of accomplishing. And I suspect this is very often the case in the use of both splint and pulley."

On the Mechanical Treatment of Disease of the Hip Joint, New York, 1873, p. 13: "On the very first intimation of a diminished ability to bear pressure, which is the great obstacle to a spontaneous arrest of any morbid process within the joint, the exigency of arresting motion

to save the joint from immediate pain causes the muscles to take on a contraction of such a rigid and permanent character as to be a condition of perpetual wounding of the parts. Their own excessive action, as well as their inelasticity, constitutes a continued source of severest injury. Hence there is established a self-continuing traumatic condition calculated to increase and prolong any diseased action once commenced in this joint; the more the disease, the more the muscular contraction and rigidity to avoid motion, and the greater the pressure and injury to the affected tissues. . . . But add motion to a diseased and compressed joint, and can we wonder at the destructive course disease of the hip joint ordinarily runs? . . . It is pressure, or motion under pressure, which is the destructive agent." The first indication is "to relieve the pressure in the joint due to muscular contraction by temporarily destroying the muscular irritability and contractility. . . . The indication for arresting motion in the joint . . . pertains only to a condition of rigid muscular contraction and consequent pressure in the joint. But no such necessity exists after the muscular rigidity has been overcome to the degree of entirely removing all pressure within the joint. On the contrary, motion in the joint without pressure is not only not injudicious, but it is highly beneficial." Pages 25, 26: In regard to the first indication, "I mean not only the increased muscular action which is incidental to the disease, with the consequent increased pressure in the joint, but all muscular action, together with all pressure in the joint, ought to be removed, as the first step of any treatment which would carry out the principle of treatment of this disease by extension and counter-extension. A treatment which purports to be this, but which stops short of relieving all pressure in the joint by means of overcoming all muscular action, is not this treatment at all, but something else far different in principle. And here is where so many think they are adopting the treatment by extension, but, not carrying it far enough to destroy, temporarily at least, the irritability and contractility of the muscles, fail of success. Either through not conceiving that the legitimate object of antagonizing the muscles by counter-force is to entirely overcome them, or not having mechanical appliances capable of producing such a result, they must necessarily fail of realizing any of the advantages of this treatment. It is not enough to stretch the muscles; they must be stretched till they yield. And they must be kept stretched and relaxed till the disease in the joint subsides." Page 38: "I am speaking of a mechanical treatment of disease of the hip joint which is capable of actually, not seemingly, overcoming—that is, temporarily destroying—the action of all the muscles concerned in the movements of the thigh, for the purpose of relieving all the pressure, not a part of it, in the joint."

On Some Elements of Diagnosis in the Different Stages of Diseases of the Hip Joint. *Medical Record*, May 8, 1875, p. 318: "I follow one indication—viz., to overcome completely the muscular action. I use the counter-extending force, not till the pain, if any exists, is relieved, but till the muscles relax."

Observations on the Mechanical Treatment of Disease

of the Hip Joint. *Boston Medical and Surgical Journal*, March 6, 1879, p. 318: "The pressure from irritated muscles at this time is a much greater evil than motion alone could be. To overcome the injurious pressure from irritated muscles is, then, imperative. Hence we must stretch them." Page 319: "We must carry extension until the muscles relax, and then we must maintain the extension until they lose their irritability and the inflammation in the joint has been given time to become retrogressive. . . . The limitation is reached at the point of time when the muscles have become soft and compressible and the interstitial movements have become completely retrogressive. From this moment reflex irritation of the muscles ceases entirely, and with it the necessity for extension."

Thomas, H. O. *Diseases of the Hip, Knee, and Ankle Joints*, Liverpool, second edition, 1876, p. 10: "Continuity of extension 'per se' is not a remedy in hip-joint disease, as I shall subsequently show; in its application it involves unavoidably a fractional degree of fixation which is sufficient to mask the evil of this ridiculous malpractice."

A Review of the Past and Present Treatment of Diseases of the Hip, Knee, and Ankle Joints, Liverpool, 1878, p. 19, footnote: "All forms of extension in joint disease involve inseparably in their application a certain amount of fixation."

Velpeau. Discussion in the Surgical Society of Paris. *Bulletin de la Soc. de chir.*, 1865, p. 126: "For twenty years I have advised extension and counter-extension in my lectures and have used it in my practice. It is an excellent method of restraining the pressure of the articular surfaces."

Volkman, R. "Distraction" was advocated by Volkman in 1865 as a means of reducing pressure between the surfaces and relieving pain. Monod, *Arch. gén.*, 1878, pp. 706, 707.

Watson, John. Discussion in the New York Academy of Medicine. *American Medical Times*, May 11, 1861, p. 310: "I placed her [patient in acute stage of hip disease] upon the straight apparatus as if she had a fracture of the thigh. I had hardly put on the counter-extension before the girl was entirely free from pain. It operated beautifully and instantly."

Willard, De Forest. Splint for Hip Injuries, including Hip-joint Disease and Fractures of the Femoral Neck. *Philadelphia Medical Times*, November 6, 1880, p. 72: "All hip-disease splints do good only by fixation."

Wood, John. On the Employment of Double Extension in Cases of Diseases and Injuries of the Spine and Pelvic Joints. *British Medical Journal*, June 5, 1880, p. 837: "By extension the pressure on the joint surfaces produced by the tonic contraction of the muscles is relieved, or almost entirely prevented."

Wyeth, John A. Hip-joint Disease successfully treated by a Combination of Sayre's Long Extension Splint and Hutchinson's Elevated Shoe and Crutch. *Medical Gazette* (New York), April 17, 1880, p. 243: "Extension is made by means of the screw key until there is freedom from pain, and a comfortable fixation of the limb. . . . I do not think that anything will secure the uninterrupted fix-

tion and extension of the joint so well as the long splint, in connection with the complete suspension of the leg."

Yale, L. M. Certain General Considerations respecting the Mechanical Treatment of Chronic Diseases of the Joints, with Especial Reference to the Use of Traction. *Medical Record*, January 12, 1878, p. 27: "When the muscular spasm is urgent, fixation can not be secured save by the use of a force as constantly acting as that which is to be overcome, and the agent best adapted to this purpose is traction, or, as it is generally called, extension. The word extension is objectionable because of its obscurity, since it is also used as the opposite of flexion." "The relief gained is not, as was formerly supposed by some, from separation of diseased surfaces. This separation is scarcely possible under any amount of force likely to be employed by a surgeon; and, again, it is very probable that whatever separation could be accomplished has already resulted from the effusion within the joint. The relief is gained simply from the prevention of muscular contractions which violently grind together the inflamed and perhaps eroded surfaces. The aim of the surgeon should then be, not to use all the traction that can be tolerated, but to use the smallest amount that will insure rest of the articulation. . . . Then, when the relief of the pain allows the muscles to relax, the direction of the traction may be changed."

SOME ADDITIONAL NOTES ON A MYXOSPORIDIAN INFECTION IN THE COMMON TOAD.

By J. B. WHINERY, M.D.,
GRAND RAPIDS, MICH.

THE increasing importance which is being attached to that class of unicellular organisms, the *Sporozoa*, in human pathology, makes it very desirable to become acquainted as far as possible with their biology. The instances of sporozoan infection in man, while increasing in frequency because of an increased knowledge of this class of parasites, are still too meager to permit of a satisfactory study of the infecting organism. We must therefore look to the lower animals in which sporozoa are frequent parasites to enable us to prosecute this study in an experimental way. In fact, in the study of the protozoa, as in the study of the bacteria, the bulk of our experimental work must be done with the lower animals for very obvious reasons.

When it is recalled that the tendency of an increasing number of pathologists is to look to these sporozoa as the exciting cause of carcinoma and other neoplasms of man, the immense importance to the pathologist of all material relating to the biology of any of these animal forms will be readily admitted. In no other line of pathological research, save bacteriology, is the value of the comparative method of study more forcibly shown than in the recent investigations on the pathogenic *Protozoa*.

At the outset of our work in this most interesting subject the importance of a uniform and precise nomenclature will be readily appreciated. In order to bring attention to

a very desirable nomenclature for one group of the sporozoa—the myxosporidia—and at the same time to bring to the notice of pathologists these very accessible and convenient objects for study, these notes on a species of myxosporidia infesting the common toad are submitted.

In the *Journal of the American Medical Association*, vol. xx, May 20, of the present year, is an article on Myxosporidia in the Common Toad, with a history and description of these organisms, by Dr. A. P. Ohlmacher, of Chicago. He has treated the subject in such a thorough manner that what may be said here will simply be slight additions to that article.

While prosecuting some studies in the pathological laboratory of the Chicago Policlinic under Professor Ohlmacher, the writer's attention was called to the myxosporidia in the toad by finding the parasites in the tubules of kidney tissue which he was studying. Following the suggestion of Dr. Ohlmacher, and under his direction, these observations upon the organisms were made. Since the organisms were found in the living animals it gave us an opportunity of studying them in the fresh state, and thus of adding some data to Ohlmacher's descriptions, which were based entirely on a study of the *Myxosporidia* in hardened tissue, no fresh preparations being available at that time.

The studies were made on the common toad (*Bufo lentiginosus* Shaw). All the animals examined were obtained from Sycamore, De Kalb County, sixty miles west of Chicago, in northeastern Illinois. There were about a dozen toads in all, and after being brought to the laboratory the toads were kept in the laboratory sink, and taken from this sink from time to time for examination.

The extent of the infection must vary with the surroundings and environment of the animals. Seven toads were examined in the laboratory—two males and five females—and out of this number one male and four females were found to be infected by the parasites. It is quite probable also that the fatality was increased by the fact of their confinement in a comparatively small space. It was noticed that during the confinement the toads became stupid and moved about but little, and that in two or three days they began to die; every day or two a toad would die. Some of them lived about three weeks. Before death no external change in the appearance of the animals was noticed, with the exception of a distention of the abdomen in some cases. On opening the abdominal wall, some increase in the amount of peritoneal fluid usually was noticed, but never a large amount in the toads examined by the writer, as was the case in the toad examined and described by Dr. Ohlmacher. The abdominal viscera showed signs of congestion. The kidneys were enlarged and in a congested state. The intestines were usually distended with gas. The parasites were found only in the tubules of the kidneys and in the urinary bladder. They were always present in the spore stage. Ohlmacher stated that they probably killed their host by increasing in numbers in the tubules, to the extent of arresting the kidney secretion by mechanical pressure. This view seems very plausible on account of the large number of parasites in the kidney tubules. The number of organisms in the tubules varied in different

specimens; sometimes only scattering tubules contained them, while in other cases large areas of tubules were filled with parasites. They were never found in the glomeruli or in epithelial cells. In the bladder the parasites were found in the folds of the mucous membrane. Ohlmacher has found them in the urine of toads collected in a clean basin during chloroform narcosis.

Dr. R. R. Gurley, of Washington, who has examined Ohlmacher's preparations, designates this myxosporid of *Bufo lentiginosus* the *Chloromyxum Ohlmacheri*, in conformity with his recent work on the classification of myxosporidia, which is based on the morphology of the spore (On the Classification of the Myxosporidia, extract from the *Bulletin of the U. S. Fish Commission*, pp. 407 to 420, July 15, 1893). According to this authority, very little is known in the literature of myxosporidian infection in amphibia. Dr. Gurley has advanced a very desirable nomenclature in the description of these *Sporozoa*, and, in order to reconcile these terms with those employed by Ohlmacher, the following table is given and a figure introduced to illustrate the parts:

Gurley's term.	Ohlmacher's term.
Shell.....	Capsule.
Capsule.....	Pole corpuscle.
Sporoplasm.....	Plasmatic mass.
Filament.....	Projectile thread.
Anterior and posterior ends. . .	Sides.
Sides.....	Ends.
Pericystic space.....	Vacuole.

Figure (diagrammatic) representing a spore of *Chloromyxum Ohlmacheri*, with designation of the various parts after the terminology proposed by Gurley. The arrows indicate the ends and sides of the spore as follows: *ant.*, anterior end; *post.*, posterior end. Right and left sides. *a*, spore shell; *b*, sporoplasm; *c*, capsule; *d*, posterior micronate projection (the valve junction ridge in optical section); *e*, valve junction ridge; *f*, anterior micronate projection with thickening; *g*, filament, much shortened.

Detailed Morphology of Spore.—It measures about 6 μ from end to end and about 8 μ from side to side. There is a slight variation in the size of spores in the same preparation. In shape the spore is slightly oval. It is surrounded by the shell, which shows a distinct striation. The striae appear to proceed from the shell of each lateral half and center at the valve junction, midway between the anterior and posterior ends. At each end of the spore is a slight

projection termed by Gurley the "micronate projection," and running between these two points is a faint transparent line called the ridge, marking the junction of the two valves. The micronate projections represent the ridge as seen in the transverse optical section. It will thus be seen that the spore is composed of two valves, the valve junction plane dividing the spore into two symmetrical halves. Two small knob-like thickenings can be seen at the anterior micronate projection, one belonging to each valve. These thickenings show well in the fresh, unstained spore. The spores often show cleavage at the anterior end along the line of the valve junction. The capsules are two in number, are round, measuring from 3 μ to 3.5 μ on an average, and are situated in the anterior end of the spore, one in each valve. A filament arises from each capsule, and, penetrating the shell, leaves the spore at the anterior end. The capsules seem to have the power of projecting and drawing in these filaments. In length the filaments often exceed four to eight times the diameter of the spore. Just after entering the spore and before reaching the capsule, they often appear in a spiral roll preparatory to being collected in the capsule. The sporoplasm is situated in the posterior end of the spore, extending to the sides, in form approaching a crescent. It does not completely fill the space posterior to the capsules. Under high power ($\frac{1}{2}$ Leitz) it appears homogeneous and finely granular. In the fresh preparations I have always been able to see the more highly refractive granules in the sporoplasm, which are designated nuclei by Thélohan. These nuclei apparently varied in number and position in fresh spores, and I was unable to find any constancy either in their number or position. The nuclei never appeared in hardened and stained preparations, and as Ohlmacher did not have the opportunity of examining the living spores when his first communication was made, this doubtless accounts for his statement that he was never able to find the nuclear structure in the sporoplasm. The true vacuole is a space in the sporoplasm and such a vacuole the writer was never able to discern in this species. Ohlmacher applied the term vacuole to the unoccupied space about the capsule ("pericystic space," Gurley); hence his statement that this spore contained a vacuole. In containing no sporoplasmic vacuole, the *Chloromyxum Ohlmacheri* agrees with other *Chloromyxidae*.

Micro-chemistry.—The parasites were studied in the fresh state, and also after treatment with various fixing and staining agents. Fresh preparations were obtained by teasing kidney tissue, and examining this in a hanging drop, or in fluid media of different kinds. In the fresh state, a dilute solution of potassium hydrate caused a swelling of the spore, and brought out the shell and filaments plainly. Glycerin acts well as a medium for the examination of the fresh spore. Probably the best medium to use in studying the hanging drop is urine from the toad. A watery solution of iodine colors the spore a uniform brown. In fixing cover-glass preparations, no advantage was gained by fixing them in alcohol and ether, or in osmic acid, over that obtained by passing the covers through a flame. In the fresh state the filaments were made plainer in fixed cover-glass preparations by a number of reagents. Methyl

blue in aqueous solution and Babes's aniline-water safranin are quite satisfactory in bringing the filaments into view. Of the many agents used in fixing tissue the following were tried: Flemming's solution, Heidenhain's mercuric-chloride solution, absolute alcohol, Carnoy's acetic alcohol, and Perenyi's fluid. In the case of all of these fixing agents the tissue was carried through by the usual methods and imbedded in xylol-paraffin. Stained preparations from tissue fixed in mercuric-chloride solution, Carnoy's solution, and absolute alcohol gave the best results. Flemming's solution and Perenyi's fluid are unsuitable as fixing agents on account of the shrinking and distortion of the spores induced by them. Numerous stains and combinations of stains were used with varying results. With almost any stain the capsules show the greatest affinity for the coloring matter, and the intensity varies somewhat in different spores. Pfitzner's safranin is especially good as a staining agent, with a striking affinity for the capsules. In the case of a double staining with fuchsin and iodine green (Russell's method), or with safranin and methyl blue (Ohlmacher's method), I was able to demonstrate the dichromophilism of the capsules and sporoplasm as described by Ohlmacher. This chromophilous reaction is a very striking and possibly significant phenomenon in these organisms.

From these studies it appears that the *Chloromyxum Ohlmacheri* is a common parasite in the common toad, at least in the locality mentioned; and that this organism possesses distinct specific features. Thus far nothing is known of the life history of these *Mycosporidia*.

LABORATORY OF PATHOLOGY, CHICAGO POLICLINIC, Aug. 25, 1893.

The Samuel D. Gross Prize.—The Philadelphia Academy of Surgery gives notice that the quinquennial prize of one thousand dollars under the will of the late Samuel D. Gross, M. D., will be awarded on January 1, 1895. The conditions annexed by the testator are that the prize "shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." It is expressly stipulated that the successful competitor, who receives the prize, shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery. The essay, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, before January 1, 1895. Each essay must be distinguished by a motto and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

The Death of Dr. Charles Warrington Earle, of Chicago, on November 19th, removes a physician well known in New York. He was a member of the staff of the Cook County Hospital and of that of the Wesley Hospital. He was professor of operative obstetrics in the Post-graduate School and had held a chair in the Woman's Medical College. He was a native of Vermont and in his forty-ninth year.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 2, 1893.

THE DEFECTIVE REGISTRATION OF CAUSES OF DEATH.

ACCURACY and uniformity in the matter of vital registration are admitted to have great value in the solution of all sanitary problems. They are, however, seldom attained, and most registration officers at the present time are not so given to boasting of such attainment as they were a generation ago. If one locality excels another in the completeness of its registration work, and the value of its tabulation, it is, in our opinion, chiefly due to the efficiency of the office of that particular place or to the enthusiasm of the gentleman who holds the office of register. It is the man who is the master, and not the slave, of his statistics who develops the excellence lying dormant in figures.

In the last Connecticut State Board of Health Report, the secretary, Dr. C. A. Lindsley, points out a cause of inaccuracy that is worthy of serious attention by all students of vital statistics. His observations are pertinent to the reports of many State boards, as well as to those of smaller offices that are susceptible of the same sort of imperfection. The difficulty we refer to may, in a word, be said to be this: The report-maker is too remote from the matter reported upon. The original certificates do not come before the register, or superintendent, or secretary, or whatever the official title may be. In Connecticut there are 168 town districts and 168 different town registers, the greater part of whom have no familiarity with the work. These persons are the legal custodians of the original death reports. The State register must report the facts that filter in to him through 168 different officials, some of them village Dogberries. The "personal equation" must inflict its self all too often upon the scientific compiler at headquarters, for, as he says, the abstracts necessarily differ greatly in accuracy, in fullness of detail, and in other important particulars. As an illustration of the carelessness, indifference, or possibly ignorance of some who prepare the abstracts, the following remarkable causes of death, reported in the abstracts, may be mentioned: puerperal fever in a boy under one year old; suicide by infants under one year of age; puerperal hemorrhage in a man over eighty years; puerperal septicæmia in a boy aged five; and childbed fever in women aged from sixty to eighty. "Effusion of head" wrecked the life of an infant under a year old, and one old gentleman, aged seventy, perished by sterility. From all this it must be evident that some at least of the town reporters are not conversant with many of the more obvious of the medical terms employed in certificates of death. Furthermore, it must be evident that the hands that pen such absurdities and blunders as the foregoing and many

others quite as misleading must also be prone to transmit mis-statements, and these in turn become the source of error on the part of those who have need to consult the death records for sanitary data.

The remedy consists in making the State superintendent the custodian of the original returns. These could then be studied, compiled, made use of to the best advantage under the eye of a person skilled in the uses of statistics. This is done in nearly all the States that reap the best results from a collection of the facts relating to "the tripod of social life—birth, death, and marriage." As matters now are, under the existing laws that govern the work of Dr. Lindsley, a single error has been known to entail, in its correction, the writing of six letters. This implies an annoying waste of energy and loss of time. A little intelligent legislation on this subject would infuse into Connecticut registration a material scientific improvement.

It is generally assumed that registration in Great Britain is nearly faultless, that during the past fifty years it has grown up into perfect system. This is far from being the fact. A parliamentary committee reported early in September concerning various defects, and their means of remedy, in regard to the detection of the causes of death that might be due to poison, violence, or criminal negligence. The proportion of uncertified deaths in England is not far from 2.7 per cent. of the total mortality; in Scotland it is as high as 5.8 per cent., and in certain small districts it is even higher. This showing is regarded as a reflection upon the coroner's system, in part, but the chief onus must be borne by the legislative branch of the government, since it is admitted that an additional money appropriation is required to supply a system of investigation of obscure deaths such as exists in Paris and other large French cities and also in Massachusetts.

The committee was pained to observe that uncertified deaths were at their maximum during those periods of life when the individual was not self-supporting, when he was not economically valuable as an earner of wages. The committee recommends that the class of "uncertified deaths" be no longer recognized, and that the necessary means be provided whereby a medical certificate shall be obtainable in every case of death where the cause is not ascertained by means of a regular physician's report. In cases where it is impracticable to have the physician inspect the body after death, a certificate of the fact of death should be supplied by two neighboring witnesses—this to be affixed to the statement of the *causa mortis* report of the attendant. The habit of handing death certificates to representatives of the deceased should be discontinued; these documents should be sent to the official register. Many other valuable suggestions are contained in the committee's report on the non-reporting of stillbirths in cases of seven months' development and on the disposal of dead bodies without official permit. It is important to every civilized community that no person shall disappear from his place without some satisfactory evidence being obtained as to the cause of his disappearance and as to the bourne whither he has been taken.

MINOR PARAGRAPHS.

INOCULATION IN TYPHOID FEVER.

In the *Deutsche medicinische Wochenschrift*, No. 41, Dr. E. Fraenkel reports a number of cases of typhoid fever treated by gluteal injections of cultures of the typhoid bacillus. Cultivation of the bacteria in thymus-bouillon very materially diminished its virulence. The cases are not published in detail, but Dr. Fraenkel is of the opinion that the treatment modified and shortened the course of the fever, although he did not see that it prevented relapses or accidental complications. Professor Rumpf publishes in the same journal the report of thirty-six cases of typhoid fever treated by gluteal injections of culture of the *Bacillus pyocyaneus*. He is of the opinion that the course of the fever is modified both as to its intensity and as to its duration.

THE ST. LOUIS AMBULANCE CAR.

It appears that the street-car ambulance service in St. Louis, of which we lately made mention, is not yet actually in operation. A bill making an appropriation for the purpose is before the House of Delegates, however, and, as we learn from the *St. Louis Post-Dispatch*, at a recent meeting of the Committee on Sanitary Affairs of that body Health Commissioner Homan cited our favorable comment on the idea, and added that he thought the first cost would be the only obstacle in the way of the project, and that when the service was once established it would work a saving of money to the city.

HARTFORD MEDICAL SOCIETY.

The medical society of the city of Hartford, organized in 1848, is to receive a fund for the erection of a building to be devoted to its purposes and to those of the medical profession of that city. It will be in memory of the late Dr. Ebenezer Kingsbury Hunt, formerly president of the Connecticut State Medical Society, in compliance with the terms of a bequest of the late Mrs. Mary C. Hunt, of Hartford, widow of the late Dr. Hunt. The medical school at Yale University will also fall heir to the sum of \$25,000 under the will of Mrs. Hunt.

ST. LUKE'S HOSPITAL.

The last annual report shows an average of 200 beds occupied during the year. The total number of days of treatment was, in round numbers, 73,000, at a total cost of \$113,000. This is equivalent to an average per-diem cost of \$1.49 for each patient. The total number of inmates was 2,100. The deaths numbered 234, of which about 80 were due to tuberculosis, directly or indirectly. The year ends on St. Luke's Day, October 18th.

ECPHYADITIS CAUSED BY ASCARIDES.

A CASE of this disease caused by an accumulation of ascarides in the vermiform appendix and its obstruction by them is reported by Dr. Gouraud and Dr. Martin-Durr in the *Gazette des hôpitaux*, No. 79. The inflammation was very intense, and resulted in an abscess which broke down and emptied itself into the bowel. An examination of the evacuated material disclosed quantities of ascarides.

THE CHOLERA MORTALITY AT MECCA IN 1893.

An officer of the Egyptian sanitary service, who was present in Mecca during a part of July, reports the prevalence of cholera

in many houses and tents, with a mortality so great that the interment of the dead was at times neglected. It is estimated that the pilgrims then in Mecca were 135,000 in number, and that at least one in ten was slain by the cholera.

THE WORK PERFORMED AT THE EMERGENCY HOSPITAL OF THE WORLD'S FAIR.

THE total number of cases admitted for treatment at the Columbian Emergency Hospital is reported to have been 18,500. There were twenty-three deaths in the institution, about equally due to medical and surgical causes. The proportion of fatal injuries among the employees was very low.

INFECTIOUS THYREOIDITIS.

E. JEANSELME contributes an article on this subject to the *Archives générales de médecine*. The case which attracted his attention was one of typhoid fever in which the symptoms of acute infectious thyreoiditis had come on about the fifth week of the disease. An abscess formed in the gland. Evacuation and microscopical examination of the contents revealed the Eberth germ.

ITEMS, ETC.

The Medical Society of the County of New York on the Regulation of the Practice of Midwifery.—The following is the report of a committee on the practice of obstetrics by midwives:

In presenting a proposed amendment to the medical laws of the State of New York involving the practice of obstetrics by midwives, the committee appointed by the Chair in April last desires to call the society's attention to the following facts:

1. There is at present no law in the State of New York for the regulation of midwives in the practice of obstetrics. Any person can so practice after registering and paying a fee of fifty cents.

2. The number of persons at present acting as midwives in the city of New York is thought to be over three thousand.

3. The number of births reported annually by midwives is within a few hundred of the number reported by physicians. That number is about twenty-five thousand.

4. In the matter of stillbirths, the percentage here is nearly three times greater than with the midwives in Berlin, where the practice is regulated.

5. There is good reason for the belief that criminal abortion is frequently practiced by some of the midwives of this and other cities of this State.

In considering means for improving the anomalous situation at present existing in this State—namely, that physicians who devote years of study in preparation for obstetric and other work are not allowed to practice until stringent requirements have been met according to law, while the most ignorant, by classing themselves as "midwives," can without question care for women passing through that perilous "physiological process" child-bearing—the committee has considered the following questions:

1. Should the practice of obstetrics by midwives be done away with altogether?

2. If so, could it be prevented?

3. If allowed, should means for the education of midwives be established?

4. How much preliminary qualification should be required?

5. Would not limited requirements, a reasonable registration

and fee, and strict limitation of their obstetric privileges, by which a large percentage of cases would be thrown into the hands of physicians, prove most feasible?

Without going too minutely into the details of the views and arguments expressed, it was the unanimous opinion of the committee that, on the one hand, the trend of obstetrical practice was and should be toward a scientific level beyond the possible attainment of midwives, and that the latter were an importation which should not be cultivated as a branch of our profession; but that, on the other hand, it would not be feasible to undertake their complete removal.

Stringent requirements as regards antisepsis and close limitation of the midwife's practice to the most normal conditions, requiring that a physician be summoned for all abnormal conditions, and the restriction of her license in not permitting her to make returns of stillbirth or treat puerperal diseases—these, it was thought, would bring about the best results.

Similar methods have been put to the test in other States—New Jersey, Illinois, and Minnesota, and in Erie County in this State—with most marked improvement. The number of midwives practicing has been reduced, the percentage of stillbirths lessened, the development of fevers greatly reduced, and criminal malpractice brought nearer the eye of the law.

Your committee unanimously proposes the following as in its opinion a much needed amendment to the present medical laws of the State of New York:

An Act to Regulate the Practice of Midwifery in the State of New York.—Be it enacted by the Senate and Assembly of the State of New York—

1. That every person practicing midwifery in any of its branches shall possess a certificate from the State Board of Medical Examiners, as hereinafter provided.

2. And be it enacted, That every person now practicing midwifery in the incorporated cities of this State shall, within thirty days after the passing of this act, personally present to the State Board of Medical Examiners an affidavit setting forth the name, nationality, age, authority, location, and length of practice, together with a certificate of good moral character from some registered physician resident of the same district; whereupon the board, on receipt of a fee of one dollar, shall issue a certificate, signed by its president and secretary and bearing the seal of said board, entitling the person named therein to practice midwifery in this State.

3. And be it enacted, That every person hereafter beginning the practice of midwifery in this State shall appear before the State Board of Medical Examiners and submit to such examinations in midwifery as the board shall require, and, if such examination is satisfactory to the examiners, the said board shall upon the receipt of a fee of five dollars, issue a certificate, the same as provided in section two of this act.

4. And be it enacted, That the person so receiving said certificate shall file the same with the clerk of the county in which she resides, and said clerk shall file said certificate, and enter a memorandum thereof, giving the date of said certificate and the name of the person to whom the same is issued and the date of said filing, in a book to be provided and kept for that purpose, and for which registry the said clerk shall be entitled to demand and receive from each person registering the sum of twenty-five cents.

5. And be it enacted, That the State Board of Medical Examiners are hereby authorized and empowered to execute the provisions of this act, and shall hold examinations of candidates for certificates in midwifery at such times and places as may be deemed by them expedient.

6. And be it enacted, That the State Board of Medical Examiners may refuse licenses to persons of bad character, or

guilty of unprofessional or dishonorable conduct, and may revoke licenses for like cause, or for neglect to make proper returns of births to the various health officers.

7. And be it enacted, That this license does not give any person practicing midwifery within the meaning of this act the right to perform version or treat breech or face presentations, or do any obstetric operation requiring instruments, or treat any abnormal condition, except in emergency, or make returns of stillbirths or puerperal diseases to the various health officers, but shall call in a qualified physician to treat the same.

8. And be it enacted, That any person shall be regarded as practicing midwifery within the meaning of this act who shall publicly profess by advertisement, by sign, by card, or otherwise to be a midwife, or who shall for a fee attend to women in childbirth, but nothing in this act shall be construed to prohibit gratuitous service in case of emergency or to the legally qualified physicians or surgeons of this State.

9. And be it enacted, That any person practicing midwifery in this State without first complying with the provisions of this act shall be guilty of a misdemeanor and shall be punished by a fine of not less than ten dollars nor more than fifty dollars, or by imprisonment in the county jail for not less than ten nor more than thirty days, or both, in the discretion of the court.

10. And be it enacted, That all acts or parts of acts inconsistent herewith be and the same are hereby repealed, and that this act shall take effect immediately.

Respectfully submitted,

Committee: { EDWARD A. AYERS, M. D., *Chairman*,
SIMON BARUCH, M. D.,
HENRY R. DEXTON, M. D.,
S. SEABURY JONES, M. D.,
HERMAN L. COLLYER, M. D.

The Prize of the American Neurological Association.—

The association offers a prize of \$200 for the best essay on any subject connected with neurological science. This competition is open to physicians who are legal residents of States in North and South America. Essays must be sent to the secretary of the association, Dr. Græme M. Hammond, on or before the first day of May, 1894. Each essay shall be accompanied by a sealed envelope containing the name and address of the author and bearing on the outside a motto, which shall also be inscribed upon the essay. Essays shall be type-written, in either the English or French language, and with the pages securely fastened. The council of the association reserves the right to reject any or all essays judged unworthy of the award. Each essay must exhibit original research, and none will be accepted that has previously been published.

The International Medical Congress.—

The chairman (Dr. A. Jacobi) of the American National Committee of the International Medical Congress, which was postponed from September 24th on account of cholera prevailing in Italy, has been notified by the Secretary General that the congress will be held at Rome from March 29 to April 5, 1894. Instructions and documents relating to the journey, etc., are promised for the near future.

Dartmouth Medical College.—

The annual graduation exercises of this school, held last week, were those of the ninety-sixth class. The school now has a corps of twenty professors and prosectors and a class of over a hundred students. Dr. Adams, of the New Hampshire Medical Society, delivered the anniversary oration.

The Death of Dr. Henry Bronson, of New Haven, re-

moves one of the senior ex-presidents of the Medical Society of

Connecticut. He was born in Waterbury in 1804. He received his medical degree from Yale College in 1827, and thirteen years later the A. M. degree. He had two terms in the professorate of materia medica in that college, amounting to seventeen years in all. Portions of his professional life were spent at Albany and at Springfield, Mass., but about fifty years ago he definitively established himself at New Haven. Among his contributions to medical literature was an historical sketch of malarial fever in the vicinity of the city where he dwelt. It is reported that Dr. Bronson left a large estate, notwithstanding the fact that he had been a confirmed invalid during the last two decades of his life. The date of his death was November 26th.

The Nursery and Child's Hospital.—

We learn that Dr. Edward L. Partridge has resigned from the medical staff.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending November 25, 1893:

BARNUM, M. W., Assistant Surgeon. Detached from the U. S. Steamer Richmond and ordered to the Kearsarge.

ROSS, J. W., Surgeon. Detached from Pensacola Hospital and to proceed home and await orders.

BALDWIN, L. B., Surgeon. Detached from the U. S. Steamer Michigan and ordered to the Pensacola Hospital.

SAYRE, J. S., Passed Assistant Surgeon. Ordered to the Michigan.

CAVELL, A. C., Passed Assistant Surgeon. Detached from the Kearsarge and granted leave for three months.

LUMSDEN, G. P., Passed Assistant Surgeon. Detached from the ironclads, Richmond, Va., and ordered to the Kearsarge.

HESLER, F. A., Passed Assistant Surgeon. Detached from the U. S. Steamer Vermont and ordered to the ironclads, Richmond, Va.

LEYS, JAMES F., Assistant Surgeon. Detached from the Laboratory, Brooklyn, N. Y., and ordered to the Vermont.

PIGOTT, M. R., Assistant Surgeon. Detached from the U. S. Steamer Kearsarge and ordered to the Richmond.

Society Meetings for the Coming Week:

MONDAY, December 4th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private), New York; Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

TUESDAY, December 5th: New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Herkimer (semi-annual—Herkimer) and Saratoga (Ballston Spa), N. Y.; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, December 6th: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Society of the County of Richmond (Stapleton), N. Y.; Medical Microscopical Society of Brooklyn;

Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, December 7th: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, December 8th: Yorkville Medical Association (private), New York; Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, December 9th: Obstetrical Society of Boston (private).

Letters to the Editor.

THE BOARD OF HEALTH AND PRIVATE PATIENTS WITH INFECTIOUS DISEASES.

16 EAST THIRTIETH STREET, November 27, 1893.

To the Editor of the New York Medical Journal:

SIR: A recent experience with the Health Department prompts me to ask if you or any of your readers can give me the information I have failed to obtain from that department. Some time ago I reported a case of diphtheria occurring in a private house. Shortly after my report an inspector visited the house and demanded to see the patient in order to obtain a culture, saying to the mother of the child that "if the physician knew his business he would have sent them a specimen." His conduct as reported to me was discourteous. I have written twice to the department asking by what right such a demand was made. To this question no answer has been received. Has there been any recent enactment which gives them such right? No offer was made to examine the sanitary condition of the premises, or to find out what precautions were being taken for the protection of the other inmates. If the board of health has made such a law they should have notified the physicians. If there had been any question of diagnosis I would have taken a culture for my own satisfaction. In their zeal to obtain this, it seems to me they overlooked matters more important than the diagnosis.

STUYVESANT F. MORRIS, M.D.

Proceedings of Societies.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of October 2, 1893.

The President, DR. WILLIAM HUNT, in the Chair.

Carbolic Acid Used in Full Strength in Surgery.—Dr.

OSCAR H. ALLIS read a paper as follows:

Surgeons in early days of antiseptic surgery attributed their success to carbolic acid. As introduced, it was employed in a dilute aqueous or oleaginous solution. For a time it was the sole antiseptic. To-day it is mainly used in general surgery as a bath for surgical instruments. Few surgeons will demand a reason for its abandonment. Few have not personally experienced its benumbing effects, and have thus been able to assign the collapse following its employment to something different than loss of blood, shock of operation, or anæsthetic.

With such an experience of carbolic acid in its dilute form I confess that I was quite astonished to learn from my friend Dr. B. F. Gardner, of Bloomsburg, that he was in the habit of using the article in its full strength upon extensive cut surfaces, and that, too, with the happiest results. As this article owes its entire value to Dr. Gardner, I will give in detail his method.

When Lister introduced his paste Dr. Gardner used it quite extensively. After an application to quite an extensive wound surface he was surprised to find it turn white, and that he had used pure carbolic acid. He therefore immediately washed the surface and dressed the wound, keeping it open until oozing had ceased. The case did so well that it inaugurated with him a line of treatment that he has extensively employed. As a typical application let me take an amputation of the female breast. After its removal and the ligation of the bleeding vessels carbolic-acid crystals, dissolved in sufficient water for solution, are applied with a sponge to all parts of the cut surface. Immediately upon the application of the acid the tissues turn white, which is a guarantee of its thorough action. The wound surface is then washed with water previously sterilized by boiling, and then approximated with provisions for drainage. This is especially necessary, as for twenty-four hours the oozing must find ready exit. During the first few days there is a slight local hyperæmia along the borders of approximation, but this declines without crisis.

Dr. Gardner claims for carbolic acid applied in official strength:

1. That no systemic absorption attends its use, and hence no danger, no shock.
2. That it is a local anæsthetic. Hence there is not as much pain after the operation.
3. That it is in a measure a hæmostatic, acting especially upon the capillary vessels.

I have taken the removal of the mamma only as an illustrative case. In all operations outside of the pleuritic and abdominal cavities, such as amputations and resections, Dr. Gardner resorts to it.

In hydrocele he lays open the sac freely, then applies carbolic acid to the tunica vaginalis, and concludes with packing or drainage. The operation is not followed by excess of any kind, and recovery is prompt. He has used it in gunshot wounds of the knee and ankle. If he gets such a case after supuration has set in he freely opens the joint, applies the carbolic acid to every part, washes out all excess freely, secures ample drainage with fixation, and confidently awaits the result. Ankylosis may follow, but this will depend on the extent of the injury, the delay in treatment, the conduct of the patient. Dr. Gardner has used bichloride of mercury, hydrogen peroxide, iodoform, etc.; none of them has answered the claims made for them; all have disappointed him, but pure carbolic acid never.

I have said that Dr. Gardner does not use this upon serous membranes—i. e., within the abdomen. I must modify this statement. In a case of strangulated hernia, in which he found patches of sphacelus—not deep, but threatening—he cautiously applied the pure acid and returned the gut. Fortunately, the strangulation had been arrested by operation in time to save the gut. Nothing eventful in the subsequent history, which was speedy.

I do not know Dr. Gardner's theory of the actions of this powerful drug, and shall attempt no explanation. The turning of the wound surface white is due probably to the coagulation of the albumin of the tissues and fluids of the wound surface, and not that the acid has a necrotic effect. That it does not produce a true destruction of tissue may be inferred that after

a large breast or thigh amputation he will have primary union and no suppuration. In its use in hydrocele a half drachm or more is injected into the tunica vaginalis, and resolution without suppuration ensues. It is possible that by its action upon the wound surface an action similar to that obtained by heat may be produced, and thus facilitate repair.

I will conclude this article by briefly stating my own experience with it.

On entering the wards of the Presbyterian Hospital I found that one of my amputations of the thigh had not done well, and looking at the stump, found it swollen and of an angry, threatening character. The seam of approximation was perfect. I therefore removed all the sutures, and separating the flaps, found them almost in a stage of gangrene. Taking carbolic acid pure, I applied it freely, pressing it into the tissues with the sponge applicator, removed the excess, and, packing the space between the flaps, renewed the dressing. This was done without anæsthetic and without apparent pain. The exposed surfaces soon began to granulate, when they were approximated and recovery soon followed. I have also frequently applied it upon a carrier with cotton to sinuses and after curetting glands.

Dr. H. R. WHARTON asked if Dr. Allis had seen carbolic-acid poisoning from the use of the agent in this way. He had never seen much trouble from the use of carbolic acid except in children. At the Children's Hospital he had seen two or three cases where its use had produced a marked constitutional effect. In one instance where a large nevus was dressed with carbolic-acid application there was a dark-colored urine and other symptoms of poisoning.

Dr. WILLIAM J. TAYLOR thought the application of pure carbolic acid to a fresh, clean surface, such as was left after the removal of the breast, was totally unnecessary. If there had been a thoroughly clean skin, clean instruments, ligatures, and hands, there would be primary union. If such a fresh surface was smeared with carbolic acid there would be a large amount of oozing. His experience with a few cases where strong carbolic-acid solutions had been used, a number of years ago, had been that healing was much retarded. As an application to suppurating surfaces such as Dr. Allis had spoken of, and where one wished a cauterizing and disinfecting action, he considered carbolic acid one of the best agents that we had, and he used it frequently.

Dr. W. JOSEPH HEARN said that if carbolic acid was applied to a raw surface, otherwise healthy, one would expect to have a certain amount of necrosis of the tissues. Some cells would be destroyed, and afford a soil for the propagation of germs.

Dr. RICHARD H. HARTE said that Dr. Levis had been in the habit of using carbolic acid for its cauterizing effect. He remembered several cases where he had used it freely, producing large sloughs over the posterior surface of the thigh.

Dr. ALLIS said that, in regard to poisoning, Dr. Gardner alleged immunity from poisoning from the fact that the application seared the whole surface and closed the small vessels, and nothing was taken into the system. Dilute solutions were rapidly taken up. In one case, where he had operated on two herniæ in the same individual, there had been a good deal of collapse following the use of a dilute solution of carbolic acid.

He was not prepared to say whether it had a necrotic action or not. He did not understand how Dr. Gardner got primary union, using it as he did, if it had such an action.

He thought that Dr. Gardner had probably begun its use with the idea that there might be left after amputation of the breast some cells which it would destroy. He did not bring this forward thinking that any one would be led to use it in these cases, but there was a big lesson in this use of carbolic

acid. There were places where it was valuable—for instance, in deep sinuses and pus tracts. He had injected it into a psoas abscess so that it would run out—probably eight ounces—without the slightest constitutional effect.

He could subscribe to what Dr. Harte had said. Care must be taken that the carbolic acid did not come in contact with the skin. If it touched the skin it would blister it, but when applied to a raw surface it did not have the effect which we should expect. In a few cases where it had been injected into the tunica vaginalis the patients had almost died, but in a large majority of cases carbolic acid pure in hydrocele effected a happy cure and without suppuration, hence without necrotic action.

In collecting some cases of accidents in the treatment of hydrocele such cases had been reported to him.

As to whether or not the application in recent surgery was necessary or advantageous, he left that for individual opinion. He had seen bichloride solution do as much mischief as carbolic acid probably could do in preventing primary union.

Dr. L. W. STEINBACH said that a number of years before he had had the pleasure of assisting Dr. Levis in the removal of an ovarian cyst in private practice. At that time the spray was used. The assistant who had charge of the spray put the carbolic acid into the bottle and the water on top of it without mixing the two, so that a spray of pure carbolic acid was delivered into the wound and on to the operator's hands. The doctor's hands became so numb that he was unable to introduce the stitches. The woman, however, made an excellent recovery.

Of course every one knew the good success of Dr. Levis in the treatment of hydrocele with carbolic acid. He was careful that none got into the connective tissue or on the scrotum. The speaker had never seen an accident in any of his numerous cases.

A Report of Three Months' Service in the Jefferson College Hospital was read by Dr. W. JOSEPH HEARN.

The object of this report was not to include every minor operation, but only those which might prove of interest.

Fæcal Fistula.—A young woman, married, two weeks after her first confinement, suffered from a strangulated femoral hernia. Her physicians professed to have reduced the hernia under ether. Subsequently an abscess formed at the femoral ring, was opened, with escape of gas, pus, and some fecal matter. Four months after she presented herself at the hospital, suffering from an almost constant escape of gas and fecal matter from a small tortuous sinus below Poupart's ligament. By means of a very small flexible bougie, the author was enabled to find the way into the bowel. He cut down on this bougie, following up the sinus until the bowel was reached. As he could feel no spur, he concluded that there was simply a small opening in the bowel. He freshened the edges and closed the wound. Twenty-four hours after symptoms of obstruction of the bowel occurred, with peritonitis, followed by death in three days. A post-mortem examination revealed that, instead of perforation of the bowel with a small opening, a large section of the bowel had been caught in the ring, and at least two thirds of the circumference had been lost in the slough. The lesson taught him in this case and in other similar cases that he had seen, that the abdomen should be opened in the middle line or outside of the linea alba, in addition to dissecting down through the sinus, in order to find the condition of the bowel and the amount of lost tissue. This had been a case for lateral anastomosis.

Cancer of the Colon.—A second case of abdominal section had the following history: A woman sixty-three years old was admitted to the ward suffering with obstruction of the bowels of three weeks' duration. The abdomen was enormously dis-

tended, and there was fecal vomiting. An incision was made in the middle line below the umbilicus. The intestines were so much distended that it was impossible to ascertain the seat of obstruction. An incision was made into the small intestines and their contents were milked out. This procedure necessarily caused much fecal matter to be spilled in the abdominal cavity. After reducing the contents of the abdomen the obstruction was easily located. It was a carcinomatous contraction of the middle portion of the transverse colon, with extensive adhesions to the surrounding parts. As it was found impossible to remove the section of bowel involved, an artificial anus was made in the right side. The colon just above the ileo-cæcal valve was attached to the abdominal wall and, as the symptoms were urgent, immediately opened. The peritonæum was so tender and brittle, due to inflammatory infiltration, that it was with great difficulty that sutures could be made to hold. The same difficulty was encountered when he attempted to close the opening made in the small intestine. The parts were so thickened that it was almost impossible to invert the intestinal walls for the Lembert sutures. The intestines were returned with great difficulty into the abdominal cavity, which was then thoroughly irrigated. The patient rallied from the shock promptly. Her temperature did not go beyond 101° F. She improved daily, and left the house in four weeks almost as well as she was before the obstruction occurred. The carcinoma had given her but little trouble before the obstruction—not sufficient to cause her to call for medical advice.

Femoral Aneurysm.—A third abdominal section was for ligation of the external iliac artery for an aneurysm involving the femoral under and beyond Poupart's ligament and a large portion of the external iliac in the abdominal cavity. The patient was a man, aged forty, and in good health. He determined to do the transperitoneal operation. The artery was tied without much difficulty by placing the patient in the Trendelenburg chair and packing the bowels, away from the point where he wished to place the ligature, with large pads of antiseptic gauze. The patient made a good recovery, and left the hospital cured. The author had two years previously ligated the femoral artery of the same limb.

Two Cases of Amputation of the Penis for Epithelial Cancer.—In one case the glands in the left groin were involved, and were removed with much difficulty. The left limb was very œdematous, due to pressure of the enlarged gland on the veins. The difficulty of removal was due to the proximity of those glands to the veins. The patient made a satisfactory recovery.

Five Cases of Hydrocele were operated upon by the open method. That is, the sacs were incised for about an inch; the edges of the sac were caught with hæmostatic forceps to prevent difficulty in getting into the proper cavity. After the cavity was thoroughly dried with antiseptic gauze, pure diluessed carbolic acid was applied to every part of the serous membrane. Then an iodoform gauze drainage was inserted and left for forty-eight hours. Should the incision be larger than necessary, a few catgut sutures could readily be introduced, to partly close the opening. The drainage which this mode of procedure admitted of insured absolute success. Anæsthetics were not necessary, as the line of incision could be frozen with chloride of ethyl, and the application of the acid or any other caustic caused no more pain than when injected. Those cases where the sac was very thick and could not collapse, or where covered with calcareous plates, were not adapted for this mode of treatment. Only entire or partial excision of the sac would cure that class of cases. The operation of laying open the sac and attaching it to the scrotum, and then packing, he never performed, on account of the subsequent deformity.

Three Cases of Varicocele with Elongated Scrotum.—He had ceased to perform the operation by the subcutaneous method. Both these patients had been operated upon by the open method, and a section (one inch) of the veins removed. The tied ends were then sutured together with catgut, which insured the shortening of the scrotum. Catgut was also used for ligation of the veins. The most satisfactory way to reach the veins was to transfix the tissues with knife or scissors, each side being lifted with a forceps as the gynecologist approached the peritonæum. It could be done rapidly and without danger of wounding the vein. With proper antiseptic precautions and properly sterilized catgut the patient would make a more rapid recovery than with the subcutaneous method. He never used drainage, but closed the serous membranes with catgut and the skin with silk.

Amputation of the Forearm for Epithelioma of the Wrist, which almost encircled the Arm.—For two years this patient had submitted to the application of caustics from a cancer curer until the pain became unbearable. The wound healed by first intention, not a drop of pus having been seen. But the pain in the arm never ceased. A multiple neurosis followed the local one after the patient left the hospital, and the patient died eight weeks after the amputation. Alcoholism could not be ascribed as a cause. Was it the continued use of the caustic applications, which several times caused sloughs, so the patient informed me, that caused exposure of the bones and the tissues between the bones?

Four Cases of Amputation of the Thigh; one for Sarcoma springing from the Periosteum of the Thigh Bone about the Junction of the Upper with the Middle Third.—The tumor measured twenty-eight inches in circumference, and approached the joint so far that an amputation of the hip was thought proper. Wyeth's pins were inserted and the rubber band was applied. The flaps were cut for hip amputation, but when the bone was reached it was found in such good condition that the head was not removed. The patient made an excellent recovery and gained much flesh. She was seventy years old and much broken in health when admitted to the hospital.

The second case of amputation was for a chronic syphilitic endostitis and necrosis of the lower end of the femur, with an old synovitis of the knee joint, in a man forty-five years of age and in an almost exhausted condition. The amputation was done at the junction of the upper and middle third of the thigh. The marrow was soft, almost fluid, and entirely disorganized, and it was not deemed proper to leave it. As the bone seemed healthy, he curetted up as far as the trochanter major, and packed with iodoform gauze. The patient suffered very much from shock during and after the operation, but from that time on he improved daily without a single untoward symptom until entire recovery followed.

The third case was that of a man aged thirty-three years, admitted to the hospital suffering from acute gangrene of the left leg. His history was that three weeks previous he had a second attack of an apparent erysipiditis under the care of Dr. W. L. Coplin. The pain, however, soon subsided in the right iliac region, but severe pain was felt down the left leg. The pain was excruciating, and could scarcely be controlled by large doses of anodynes. Soon after the pain began it was noticed that discoloration of a linear character occurred. It followed the course of the superficial nerves and apparently involved only the skin. Soon gangrene of the entire limb occurred, with great depression of the nervous system. A line of demarcation formed above the knee, and amputation was advised. The limb was removed at about the middle third of the thigh. The operation was followed by great shock. Very little blood was lost. He rallied for a few days, when gangrene commenced in

the right limb. At the same time it was noticed that there was no perceptible pulsation in the left radial artery. He sank slowly and died at the end of ten days from an extensive gangrene of the right leg. His previous history was not good. He suffered from chronic alcoholism. He did not suffer from disease of the valves of the heart, but from a fatty heart. An embolus was the apparent cause of the gangrene.

The fourth case was that of a boy aged twelve years, who previous to this illness never was sick. On April 1st he began having pain in the left knee, and was treated for rheumatism. Soon the swelling involved the knee joint as well as the whole leg below. His case was then supposed to be one of acute cellulitis, although there was no history of injury or any previous abrasions. He was admitted to the hospital, and several openings were made in the leg and large quantities of pus evacuated. His temperature fell for a few days, but soon arose to 103°, and he was slightly delirious. Then it was found that the joint itself was involved. It was opened and a large quantity of purulent sanguinolent fluid escaped. Still the temperature continued above normal, and the boy was still delirious. Other pockets of pus were looked for and opened. Bedsores were threatened, and his condition grew worse. At the third operation it was discovered that the boy was suffering from epiphysitis of the tibia. Necrosis at the epiphysis had occurred. As the knee joint was disorganized and the leg from the ankle to the knee was one mass of suppuration, an amputation was advised and accepted. He bore the amputation well, and almost from that day his delirium ceased. The wound healed promptly without suppuration. Very little was said of epiphysitis in the text-books. The author thought this disease occurred more frequently than we were aware of, though suppuration and necrosis were very rare. He had the history of three other cases, though the symptoms were of a much milder type than in the case just mentioned.

Floating Cartilage of the Knee Joint.—The cartilage was exhibited. Its dimensions were an inch and a half by three quarters of an inch. The man, aged forty-five years, suffered for many years with what he supposed to be rheumatism in his left knee. It had never impeded his locomotion very much. For a long time it must have been too large to impinge itself between the tibia and femur. Its position was on the left lateral aspect of the knee joint. The author cut freely down on it and removed it without difficulty, as it was not attached to any of the fimbriae of the synovial membrane. Considerable synovial fluid escaped. The synovial membrane was closed with catgut sutures and the skin as usual. No drainage was used. He made a good recovery without ankylosis.

Neurectomy of the Infra-orbital Nerve in a Lady of Seventy-three Years who had Suffered Many Years from Neuralgia.—Three years previously the author had removed the inferior dental nerve for her, with relief for two years. He removed the entire nerve by a trephine opening at the angle of the jaw to the mental foramen. After two years the pain returned in the infra-orbital nerve. This was removed by making a V-shaped notch in the lower border of the orbital bone down to the foramen. By that means he was sure to secure the nerve with all its filaments. Then, lifting up the eyeball with a retractor and breaking through the thin floor of the orbit, he was enabled to break off the nerve as far back as its origin. Very little deformity followed the removal of the wedge-shaped bone. It was now five months since the operation, and there had not been any return of pain.

Amputation of the Tongue.—The patient was a man, aged seventy-three years. He suffered for many years with papilloma of the tongue, shown in small white plaques. These were partly removed by transfixing with fine needles and tied off.

When admitted to the hospital about one third of the tongue was infiltrated. It was of twice its normal thickness, very hard and painful. The glands at the angle of the jaw were also involved. The tongue was transfixed near its tip, and a strong ligature drawn through to give control of it. The patient was placed in a Trendelenburg chair and the head so depressed that no blood could enter the trachea. After etherizing, chloroform was used during the operation. Those who had not used the Trendelenburg chair for operations about the face, nose, and fauces could scarce appreciate its usefulness in preventing suffocation from blood entering the trachea. It prevented the many interruptions to the operator on account of that accident. It did away with the necessity for tracheotomy. With the tongue elevated and pulled strongly forward it controlled hemorrhage, as suggested by Heath. Then, with a pair of scissors or a knife, the mucous membrane was divided in a smooth, even, curvilinear line at the junction of the tongue with the floor of the mouth. The object of this line was for the subsequent attachment of the upper portion of the tongue to it. After the tongue was freed as far back as necessary ablation was commenced. With a pair of scissors the tongue was divided by a series of snips until one of the lingual arteries was reached, when it was quickly caught and tied. The pulling forward of the tongue so controlled hemorrhage that but a few drops of blood escaped. Before the next artery was reached another ligature was drawn through the stump, that it too might be under control when the tongue was divided. The stump was then brought forward and sutured to the mucous membrane of the floor of the mouth. By this method there was very little surface exposed for absorption of septic material, and the prevention of septic pneumonia was greatly enhanced. This patient was fed with a tube attached to the nozzle of the feeding cup, and by that means the food was placed far back in the fauces and did not come in contact with the wound. The enlarged glands were removed, exposing the large vessels of the neck. The patient made a rapid recovery. The stump and floor of the mouth united rapidly, and in six days all the sutures were removed. He suffered much from shock after the operation, but soon rallied. About half of his tongue was removed.

Resection of Knee Joint.—A woman aged twenty years had suffered for ten years from traumatic synovitis. Her general health was good. There was no history of tuberculosis. When the joint was opened an inflammatory erosion of the entire joint surface was found. The ends of both tibia and femur were sawed off. Temporary fixation of the bone was made with catgut sutures and a plaster splint applied. Recovery satisfactory. She left the hospital in eight weeks with good union. She was directed to continue to wear a light splint for a few weeks longer.

Four Amputations of the Mammary Gland for Scirrhus.—In each case the axilla was opened and all its contents were removed. Fat was removed, regardless of the fact that in two cases no enlarged glands could be felt. Yet in both cases, when the axilla was opened, minute glands could be distinguished in the fatty material removed. He operated in all cases of carcinoma of the mammae where the disease had not so far advanced that its removal was impossible. This rule applied to chronic or fibroid scirrhus as well as to the acute variety. He felt it was more beneficent to the patient to let her die of internal cancer than to die of exhaustion due to local ulceration, with all its physical and mental distress. However much confidence the patient might have in her family doctor, who advised her not to have it touched with the surgeon's knife, sooner or later she would disobey his instructions and consult a surgeon, or else fall into the hands of the cancer doctor, with his escharotics. Which caused the greatest physical suffering?

Five Cases of Harelip.—One of these cases was simple. Three of the cases were complicated with cleft palate, both hard and soft, and one case with a double cleft, with the intermaxillary bone projecting. In this case the author removed the intermaxillary bone, believing with Rose that it interfered with the proper approximation of the lateral maxillary bones. The teeth that formed in it were never perfect and were ever useless. He did not use harelip pins in approximating the parts, but used silkworm gut, both at the vermilion border and at the cutaneous surface. He used either catgut or silk sutures for the intervening parts and the mucous membrane. The advantage of the silkworm gut over pins was that it could be left in longer without cutting or sloughing and supported the parts equally well. He never operated on a child under one month of age. There was no necessity for it, and union was much less certain.

Four Cases of Suprapubic Cystotomy.—There was one case of chronic cystitis of ten years' duration, with a small phosphatic calculus, also one of a foreign body in the bladder, part of a soft catheter, and there were two cases of stone in the bladder. The specimens were shown. The largest stone was from a male patient aged sixty-one years. He suffered for six years with all the symptoms of stone, but his sedentary habits made it endurable until a few months before he was admitted to the hospital. The stone weighed five ounces and was $7\frac{3}{4}$ inches in its greatest circumference. It was smooth, and to that fact was probably due his long tolerance of it. It was probably a uric-acid calculus with a phosphatic crust. The author had formerly been prejudiced in favor of lateral lithotomy, as he had always operated by that method. Now he was convinced that in adults the proper treatment was either suprapubic cystotomy or lithotripsy, the choice of treatment depending upon the size of the stone or the condition of the bladder and kidneys. He had never crushed a stone in a young child, yet he thought it the proper treatment.

Dr. ALLIS asked Dr. Hearn if he had seen any sloughing in the cases of hydrocele where he had used carbolic acid.

Dr. WILLIAM J. TAYLOR had had the pleasure of seeing Dr. Hearn operate in the case of intestinal obstruction referred to. He never had seen such distention of the intestine. The small intestines were larger than the average colon, and the tissues were so soft that the sutures tore out. It was simply a miracle that the woman survived.

Dr. W. W. KEEN said it was impossible to refer in detail to the five series of cases which Dr. Hearn had reported from a service of eight or ten weeks, but there were two points to which he would like to call attention. One was the use of the Trendelenburg posture in all cases of operation about the mouth and nose. A preliminary tracheotomy had often been advised and had been done in these cases. Of course, tracheotomy was not one of the most serious operations, but it did add to the complications. As Dr. Hearn had said, the speaker believed that the use of this posture would practically do away with preliminary tracheotomy in most cases, and always if the tracheotomy was for the purpose of preventing blood entering the larynx and lungs.

He had noticed also with much pleasure that Dr. Hearn had drawn attention to the importance of uniting the mucous membrane after removal of the tongue. He thought that this was of great importance, in order to avoid as far as possible any opportunity for septic infection. In removal of the lower jaw in a number of cases he had endeavored to unite the mucous membrane so as to cover in the raw surface entirely. If we did that there was no opportunity for infection of the system.

These two points in the surgery of the mouth were of great importance, and it was only in late years that he had recognized

their importance; but experience had taught him the immense benefit to be derived from these procedures.

Dr. HEARN would state that he had never seen sloughing from the use of pure carbolic acid. In one case, where the surgeon introduced a dilute solution, sloughing followed, and a few days later the testicle could be seen. Where he had used pure carbolic acid he had never seen any accident. He had always injected it until he had begun this procedure of opening the sac. He had never seen the latter operation fail. The opening permitted thorough drainage and was sure to succeed.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, Dr. MORRIS J. ASCH, of New York, in the Chair.

(Continued from page 639.)

Recurrence of a Laryngeal Growth at a New Site.—Dr. R. P. LINCOLN, of New York, read a paper with this title. (To be published.)

Dr. J. SOLIS-COHEN, of Philadelphia: This is a very interesting case. I should like to take this opportunity to place on record the final result of a case which I reported a good many years ago. It was a patient upon whom, in 1867, I performed laryngotomy and removed an epithelioma. The patient died from hemiplegia during the past year, having had no recurrence. While I have seen very few recurrences of papillomatous growths, a few very remarkable instances of it have come under my observation. For instance, I have at present under my care a school teacher who had several small, white sessile papillomas upon one vocal band, and while I have been, so to speak, in the act of removing them, I have absolutely seen other papillomata appear from the opposite ventricle and upon the corresponding vocal band. Some few years ago I published in the *International Clinics* a lecture before my class on the occasion of removing from a patient a cannula which had been worn several years for recurrent papillomata. I had opened the larynx two or three times and the trachea once to remove recurrent growths, but without permanent relief; and the patient had been compelled to wear the cannula for ten or eleven years before I was able to remove it definitively. I believe that, in the majority of cases, recurrence is due to incomplete removal of the original growth. The patients often live far distant from the operator, and leave before he is through with them. Small portions of these growths, too, are easily left behind. I believe that the skillful laryngologist is just as competent to remove these growths by the intralaryngeal route as the skillful surgeon is to remove them by external methods. Small particles of the growth may be left behind with either method. That is why in the older days we were in the habit of using the acid nitrate of mercury upon tissues whence we had removed papillomas. Now we use lactic acid. I think, if we can supervise the patient long enough after operation, we are fairly safe from late recurrences. There is no reason, however, why a new growth should not spring up from another portion of the larynx than that which has been the site of the earlier growths. I have long been of the opinion that the majority of these cases are due to excessive granulations, following erosions and lacerations, which eventually become organized. These erosions of the larynx are apt to recur, and then the same condition of affairs will be repeated—exuberant granulations and the production of papillomata.

I will mention here a case which I hope to show you before the session closes. One of our members removed a papilloma

of the larynx eighteen years ago. The patient remained free from recurrence until a few years ago, when a malignant growth appeared at the site of the previous papilloma. The patient had a catarrhal laryngitis, with exfoliation of the epithelium and erosions of the mucous membrane, and it would be interesting to know whether the malignant growth took its origin at the cicatrix—if there was a cicatrix—or upon the site of the former papilloma, which raises the question whether the cicatricial or scar tissue present was rendered more vulnerable by the catarrhal condition and gave way first.

Dr. F. I. KNIGHT: I have long recognized a form of papilloma which, when we begin to operate on it, we feel will be permanently removed, and then again another variety which is prone to recur. The first kind are the small, isolated growths, the rest of the larynx being perfectly healthy; the other variety consists of the multiple growths, and with these we feel pretty sure that a recurrence will take place. Such recurrences may happen repeatedly until, after a long lapse of time, the growths cease, as in the case reported by Dr. Hooper. It seems strange to me that we do not get recurrences oftener, because, in operating with the forceps or loop or by other methods, the operation necessarily is not a perfectly clean one. In the majority of cases more or less of the growth is left behind. It has often been a matter of congratulation with me that recurrences do not oftener occur. In the isolated cases I have generally succeeded in getting along with one operation, but in the multiple form there has almost always been a recurrence. Dr. Lincoln's case appears to have become altered in character, changing from the isolated to the multiple form. Perhaps the change in the mucous membrane, as time has gone on, induced this tendency to the recurrence of multiple growths.

With regard to operating on papilloma in children, it seems to me that thyrotomy should not be performed. Tracheotomy may be necessary, and the tumor left for a time, or it can be operated on laryngoscopically in a great many cases under ether.

Dr. DELAVAN: I have often been struck by the fact that in some cases of apparent papilloma the diagnosis is extremely difficult. In one such case which came under my observation some years ago, and was also seen by Dr. Beverley Robinson, the appearance of the growth and the intralaryngeal symptoms all pointed to papilloma. Thyrotomy was performed, and, although the interior of the larynx was fully exposed to view, we still thought the case to be one of papilloma. The growth proved to be an epithelioma. The appearance of these tumors is often deceptive, and their recurrence may indicate more than a simple papillomatous growth. Under the microscope the deeper structures may show a different condition of affairs. The tendency to repeated recurrence should always suggest the possibility of a more serious disease than simple papilloma. I remember one patient, an Irishman, about twenty-four years old, in whom the papillomata seemed to recur more rapidly than they could be removed. As soon as one was taken away several others would appear. Dyspnoea was so urgent that a tracheotomy was indicated; the man, however, would not submit to it and died very shortly after.

In those cases of persistently recurring papillomata where the recurrence takes place at short intervals, we must bear in mind the possibility of more serious disease.

Dr. MACKENZIE: I have very little to add to this already voluminous discussion except to say that, in pursuing the question of the causation of this class of growth, we are still groping very much in the dark. The ordinary causes which are given—for example, that by Morell Mackenzie, years ago, viz., hyperæmia—are hardly sufficient to account for their presence, as we see them in cases in which there is absolutely no hyperæmia.

I think hyperæmia has nothing to do with their causation in a large proportion of cases. Another thing which militates against the hyperæmic theory is that we see papillomata in the presence of anæmia, which is just the opposite condition to hyperæmia. Especially is this the case in tuberculosis. Their presence here, however, may be diathetic, and not due to local causes.

I would call attention to the great frequency of papillomatous growths in the upper air passages of the negro race. There seems also to be a greater tendency to recurrence among negroes. They often spring up like mushrooms after removal. One of my patients has been wearing a tracheotomy tube on account of them for seven years. I think that in many cases of papilloma we meet with among singers whose vocal culture has been poor there is something wrong in the apparatus of voice production. We know comparatively very little about vocalization and the complex mechanism of the separate fibers of the vocal cords, and I have no doubt that some of these papillomata of the cord originate as a result of faulty vocal mechanism.

I think Dr. Delavan has called our attention to an extremely important point, and it is my opinion that we should never remove a growth from the larynx or anywhere else, no matter how sure we are of its character, without submitting it to the microscope. I think that such a course is demanded by the scientific accuracy in diagnosis prevailing at the present day, and we should submit all cases, especially if they are at all doubtful, to a microscopic test.

Dr. F. I. KNIGHT: I should like an expression of opinion from the members present in regard to the development of epithelioma in cases which were supposed at first to be simple papilloma. It would be a very easy matter for every gentleman present to give us his experience in this matter. I have seen but one case where I thought I had to deal with a simple papilloma in which malignant disease was proved to exist afterward.

Dr. J. SOLIS-COHEN: The case I referred to in my previous remarks—the patient who died twenty-five years after operation—is one in point. In that case a microscopical examination was made. In other cases that have come under my observation I suppose I may have been deceived, because in my early days we did not submit specimens of all these growths to the microscopist. In the cases mentioned, however, the tumor grew very rapidly. It was examined by Professor Da Costa and by the late Dr. Woodward, of the United States army, who was probably the best microscopist of his day. Both of these gentlemen pronounced it epithelioma. I then determined to open the larynx and remove the growth, which I did, together with the vocal band and the whole of the ventricle, cutting into the sound tissues. As no other cases of epithelioma of the larynx had been reported in which the patient lived for five years after operation, I was for a time inclined to believe that a mistake in diagnosis had been made in my case. Since then, however, we have learned that such patients have survived for longer periods than five years, and I now believe that this case might have been one of epithelioma. I have seen other cases which at first had all the macroscopical appearances of papilloma, but which, after being picked at and pulled at, have proved to be really malignant growths, thereby accounting for the apparent recurrence.

The President: I would suggest that the question raised by Dr. Knight would be more properly discussed in connection with Dr. Simpson's paper, and if it be satisfactory to the fellows we will defer it until that time.

Intubation in the Adult.—Dr. G. M. LEFFERTS read a paper on this subject (To be published.)

Dr. W. K. SIMPSON: I have had considerable experience with adult intubation. The subject has been so thoroughly covered by Dr. Lefferts that there is little to add. The instruments employed in intubation, both for children and adults, are the result of years of experimentation before they were brought to public notice. Every attempt that will be made to modify the intubation tubes has already been gone over. A slight modification has been made in the lower aspect of the smaller tubes, it having been broadened somewhat.

The technique of the operation in adults differs somewhat from the technique of the operation in children. We have a different type of cases to deal with. We must remember that in the adult the epiglottis is much further away from the finger and is more difficult to hold in position. In cases where a tracheal cannula is worn, when we attempt to introduce the finger, we receive no aid from the elevation of the larynx. The instrument in the adult is best introduced by the use of the mirror. In children it is introduced through the sense of touch. In the adult the parts can be sprayed with cocaine, and then, with the mirror in the left hand and the instrument in the right hand, the latter is introduced and you can see it enter the larynx. This is a much better plan than to try to introduce it blindly, as we do in children. Its removal also is much better accomplished by the aid of the mirror.

I was not familiar with the fact that the statement had been made that intubation in the adult could be employed as a means of curing abductor paralysis of the cords in the fullest meaning. I have seen it suggested, however, that such a condition might be improved by this procedure, as the tube would produce a certain amount of pressure and would tire out the tendency to muscular spasm. I have employed the intubation tube in a case of fracture of the larynx with very good results.

Dr. ROZ: I have listened to Dr. Lefferts's paper with much interest. I have had some little experience with adult intubation, and have published one case of syphilitic gummata of the larynx in which it was employed where the dyspnea was so pronounced, and had been for two days, that the patient was well-nigh exhausted. This case I saw two years ago last February, reported it to the Central New York Medical Association the following June, and published it in the *Buffalo Medical and Surgical Journal* for July, 1891. As some of you may not have seen the report, and as it was an exceedingly interesting case, I will briefly relate it: The patient, a woman, had been treated by an irregular practitioner for some time for "catarrh." Her gradually increasing dyspnea, however, soon became so great that a regular practitioner was called and I was sent for to see her in consultation. Finding the patient in an almost breathless condition, I introduced by the aid of the mirror a laryngeal tube, which gave instant relief. The extreme stenosis in this case was caused by a gumma located under the left vocal cord, and pressing it upward and over against the opposite cord. The woman was at once placed on active antisyphilitic treatment, and on the fourth day the gumma had so much subsided that she coughed out the tube, and, as the breathing was quite free, it required no reintroduction.

I have also practiced intubation in one case of tubercular laryngitis associated with pulmonary tuberculosis. The patient was a young lady twenty-two years old. The infiltration and chronic inflammation of the larynx had caused an ankylosis of the arytenoid articulations. The cords were immovable and so closely adducted as to cause urgent dyspnea. I saw no way of relieving the dyspnea except by intubation or tracheotomy. The former operation was decided on, and at once gave relief. After a time the tube caused so much irritation that I had to remove it, but it had so dilated the larynx that for two or three days breathing was quite free. When the dyspnea re-

turned, the tube was reintroduced, but could only be retained for a short time, owing to the irritation and cough excited. I was then obliged to do tracheotomy, but the patient died soon after from pulmonary tuberculosis. This is the only case in which I have performed intubation when there was a tuberculous condition of the larynx. It is not well adapted for these cases, owing to the irritable and sensitive condition of the larynx, although it may be of special service in relieving impending suffocation and permitting the employment of thorough curettement and the application of lactic acid to the infiltrated tubercular tissue, or when the means for performing tracheotomy are not at hand.

Dr. DELAVAN: I was very glad to hear Dr. Lefferts emphasize the importance of special skill in the performance of intubation. I believe that a man who has intubated but two or three times will not by any means get the good results that Dr. O'Dwyer and other experts in this line have obtained. The insertion of these tubes takes long practice, and the preference should be given to the man who has had the most experience and who has the best educated touch.

Dr. LEFFERTS: Dr. Delavan's remarks are timely and to the point. I have alluded in my paper to the importance of the trained hand in performing intubation.

In reply to Dr. Simpson's remarks regarding adult intubation, I would state that I spoke of the technique of the operation in my paper read three years ago, fully covering every one of the points mentioned.

Regarding the use of the word "cure," which has been criticised in connection with the treatment of bilateral abductor paralysis by means of intubation, I would say that I have heard and seen that word repeatedly used, and I saw fit in my paper to criticise it adversely. It has been said that a cure of such paralysis can be made by means of intubation tubes. I do not believe that this is possible.

Remarks on Congenital Defects of the Face, with Exhibition of a Rare Form of Cleft Palate.—Dr. HARRISON ALLEN read a paper with this title. (To be published.)

Dr. WRIGHT: I have been very much interested in Dr. Allen's remarks. It seems to me that the late explanation that has been made, particularly by some French and German writers, regarding these deviations of the septum is very plausible indeed. We see so many of these cases that give no history of any severe injury that it has weakened our faith in the belief that they, as a rule, are due to traumatism. On the other hand, there are cases which are clearly due to a blow on the nose, with no history of previous stenosis. As regards the bony septum, to which probably Dr. Allen refers, it is almost incredible that any injury could be severe enough to cause deviation of it, because it is so well protected by the soft parts. The highly arched palate that we see in these cases, and see so often in the Caucasian race and so seldom in the negro and Indian races, leads us to a solution of this problem. It is probably due to evolutionary changes in the development of the bones of the face, and this has been dwelt on by some French observers, who show that the approach of the floor of the nose or the bony roof of the dental arch to the base of the skull has been greatly increased, and, in order to allow the septum room for its superfluous tissue, it must undergo curvature.

Dr. DELAVAN: Experiments made on rabbits have tended to confirm the theory that these deflections of the nose often were not so much due to traumatism as to defective nutrition. One of the chief of these well-known experiments consisted in stopping up one nostril in the rabbit until the animal attained its maturity; there was then found to be a distinct difference between the two sides of the face.

I have for years taught that retro-nasal obstruction or nasal

obstruction which would deprive the nose of its normal amount of air would produce this same result. I think that very often in these cases, where one nasal cavity is very much more spacious than the other, the nutrition of the defective side has been interfered with. Traumatism, in my opinion, while an important factor in the etiology of nasal deformities, is not the sole, nor in fact the chief, cause of many of these nasal and septal asymmetries, and I think that we can not recognize the fact too thoroughly.

Dr. Allen's paper has been a most interesting one. There is probably no one else who could have instructed us to the same extent and in quite the same way.

Dr. MACKENZIE: This matter can be simplified by dividing the causes of such deviations into congenital and acquired. Most of them are of congenital origin, but of those which are acquired, the majority are due to traumatism. I fully agree with Dr. Allen in what he said as regards the asymmetrical condition of the nasal cavities.

Dr. PORCHER: One word about the causes of deflections of the nasal septum. A great many explanations have been given to account for their presence, and it appears to me that traumatism is one of the least frequent of all the causes. Most of these deflections, I think, are due to inflammation of the subchondritic type or otherwise, and the curvature occurs as a necessary result in order to make room for the tissues resulting from swelling and inflammation. As it is impossible for the septum to extend itself in an upward or downward direction, it must necessarily become deflected either to the right or left.

Dr. ALLEN: As regards the point made by Dr. Porcher, that we may have deviations of the septum from inflammatory processes, I agree with him. A congenital condition of this kind may be made very much worse by acquired conditions. All these elements may be present in the same case. One does not exclude the other.

That we may have elevation of the hard palate with obstruction of the nasal respiration is undoubted, and one can well be surprised at the rapidity with which these deviations occur. Sometimes the change occurs very rapidly after an attack of acute influenza or "cold" in persons whose nutrition is poor. I have seen children with acute amygdalitis followed by acute coryza or rhinitis develop a depression of the sternum and an elevation of the ribs in the upper part of the chest within a fortnight.

In the remarks I made I did not cover the whole ground of deviations of the nasal septum, but limited myself to a few statements. It goes to show how very complex the subject really is. There is much work still to be done on the subject before we understand all the causes which lead to impeded nasal respiration and the etiology of deformities of the face.

On Some of the Manifestations of Syphilis of the Upper Air Passages.—Dr. J. H. BRYAN read a paper on this subject. (To be published.)

Dr. MULHALL: I must say in friendly criticism that the supuration of the tonsil in the second case narrated by Dr. Bryan might have been coincident with the syphilis, but independent of it. Suppurative amygdalitis, as caused by syphilis, is something new to me. The author has not furnished sufficient proof to establish the fact that the suppurative amygdalitis was caused by the syphilis.

I also desire to say a word about the notched teeth which were absent in the case of hereditary syphilis. I was associated with Mr. Hutchinson for three years as his assistant, and saw many cases of hereditary syphilis. The disease appears to make much greater ravages in the European subject than in the American. Strumous disease and rickets are also much more common over there, due to the defective nutrition of the

children. The nutrition of the poorer class of children is much better in this country than it is abroad. I have seen a number of cases of hereditary syphilis here in which the notched teeth were absent. Such teeth are partly the result of the syphilis and partly of the defective nutrition. I do not know how otherwise to explain the relatively much larger proportion of notched teeth in hereditary syphilis as observed abroad than here.

Dr. WRIGHT: I think that very frequently we are too easily deceived by the patient's statements regarding the specific nature of certain lesions. I know that in one case my credulity has lately received a severe shock—a case of nerve deafness in a young woman. Every possible means was adopted to get a history of syphilis, without result. The patient was one of the most prepossessing and modest appearing of women. Her mother gave an indirect history of syphilis, and the patient improved under the use of potassium iodide. She afterward came under the care of a gentleman of very insinuating ways, and finally admitted to him, in a fit of tears, that she had suffered from some of the symptoms of acquired syphilis after having laid herself open to infection.

I think Dr. Knight will recollect another case in which the microscopical examination and the clinical history all pointed to a sarcoma of the turbinated, and when we were just prepared to remove the maxilla a specific lesion appeared on the shin bone. Late hereditary syphilis is uncertain ground.

Dr. O. H. KNIGHT: In the case referred to by Dr. Wright the diagnosis of sarcoma of the inferior turbinated body was confirmed by the microscope, an examination having been made by several experts independently. The lesion on the crest of the tibia was a periosteal gumma. The intranasal tumor disappeared coincidentally with the latter under the influence of large doses of iodide of potassium.

Dr. MACKENZIE: Dr. Bryan, in his paper, has referred to some work which I did thirteen years ago on the subject of congenital syphilis of the larynx. I have nothing to add except to say that I then stood alone in the position which I took in the paper; since then, I think, the truth of my propositions has been quite generally conceded. Still, every now and then I meet with adverse criticism of my researches. I wish to say here that it is not in the throat clinics that we find cases of congenital throat syphilis, but in the poor houses and children's hospitals. My observations were carried on in the great children's hospitals of London, where almost every third case was one of congenital syphilis. In that way I collected one hundred and fifty cases, an analysis of which formed the basis of my paper. I wish to make this statement so that if one meets with adverse criticism of my paper he will understand how my material was obtained and where it was obtained. During my term of service at the London Throat Hospital I do not think I saw over eight or ten cases, but when I went to the Children's Hospital I saw a great many cases daily. I will also state that in my clinic at the Johns Hopkins Hospital I have recently met with quite a number of tertiary lesions of the larynx in hereditary syphilis. Morell Mackenzie once called my attention to the fact of the absence of the characteristic notched teeth in cases in which the throat was involved. I can not say whether that is so or not; I analyzed seven cases after the matter was brought to my attention, and in four of them the notched teeth were absent.

Dr. BRYAN: While the criticism made by Dr. Mulhall is very just and may be true, still the patient had been suffering with throat symptoms for several months before he came under my care; they came on in June and I saw him in October. The lesion did not present any of the other symptoms of suppurative amygdalitis. I would like to ask Dr. Mackenzie whether he

still adheres to his former belief that the laryngeal symptoms in these cases are as common as he supposed them to be.

Dr. MACKENZIE: I do.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

The Medico-electric Eye-bath in the Treatment of Scleritis and Episcleleritis.—Norsa (*Arch. of Ophthalm.*, xlii, 1) describes the method of using the eye-bath and the manner in which it works as follows: A two-litre glass vessel filled with a lukewarm one-half-per-cent. solution of lithium salicylate is placed two metres above the head of the patient. This reservoir communicates by means of a rubber tube with an ordinary eyeglass; at the bottom there is a perforation through which a metal tube is passed. The outer end of this is fastened to the rubber tube; the inner end projects about half a centimetre above the opening of the eyeglass. A small stopcock placed on the metal pipe serves to connect or to disconnect with the water reservoir. There is also an opening in the side of the vessel provided with a stopcock, in order to let off the water. An electric apparatus provided with a galvanometer is required for developing a constant current, and also a myriamperemeter to regulate the exact strength of the current. One electrode communicating with the metallic plate, properly covered and dampened with salt water, is laid upon the cervical sympathetic, while the other is connected with a small screw on the metal covering of the eyeglass. It is immaterial whether the positive or the negative pole is placed on the eye or glass. This can be regulated by the sensitiveness of the patient. The electric bath is applied to each eye for five minutes, and this treatment may be repeated every day.

The Treatment of Trachoma.—Knapp (*Arch. of Ophthalm.*, xxi, 1) sums up the results of his observations as follows: 1. Rapid, perfect, and permanent recovery by expression alone, or expression followed by a short course of mild caustic treatment, takes place in the majority of instances. 2. Imperfect recovery, with more or less shrinkage of the conjunctiva, is the common issue of old, neglected cases of inflammatory trachoma. 3. Relapses sometimes occur, and are in general promptly cured by a second expression. In a few cases a third expression is necessary. 4. The operation itself neither destroys nor injures an eye. The mechanical treatment, with or without scarification and impregnation of the lid with corrosive sublimate, does not cure all cases of trachoma, but it benefits and cures the great majority and always shortens the recovery. In rare instances it converts a simple trachoma temporarily into an inflammatory trachoma, but injures no case permanently.

The Histology of the Retina.—Fromaget (*Archives d'ophthal.*, December, 1892) finds that a large number of the nerve fibers end in the internal reticular substance, where it becomes impossible to follow them. There is no apparent continuity between the nerve-cells, and the connection between the different layers of nerve-cells is made by two plexuses—one called the cerebral or internal reticular plexus, the other called the basal or external reticular plexus.

The Modern Operations for Strabismus.—Wecker (*Arch. d'ophthal.*, January, 1893) states the following objections to the old method of operating exclusively on the deviating muscle: 1. It is often necessary to operate three and even four times for slight deviations. 2. The tenotomized muscle is thus materially weakened and the tendency to secondary squint decidedly

increased. 3. The eye tends to protrude by reason of the laceration of its capsule, the aruncle sinks, and secondary divergence occurs. The offending muscle must not be displaced backward without compensation, and this should be effected by an advancement of the sheath. The measure of the displacement backward of the muscle can only be regulated by the greater or less detachment of the capsule, and here the weakening by the displacement of the insertion of the capsule of Tenon must be very carefully considered.

Anatomical Investigations in the Angle of the Anterior Chamber and Schlemm's Canal.—Rochon-Duvigneaud (*Archives d'ophthal.*, February, 1893) gives the following résumé of his researches: The angle of the anterior chamber in man is the homologue of the cilio-scleral space in mammals and which corresponds to Fontana's space. This assimilation is based on comparative anatomy and embryology. The angle of the anterior chamber in the human fetus is filled by a fine connective-tissue network, exactly equivalent to the cilio-scleral trabeculae (ligamentum pectinatum) of mammals, and destined in the adult to be entirely absorbed. The cilio-scleral space contains two different systems of trabecular network—the sclero-corneal system and the cilio-scleral system. The sclero-corneal system alone is connected with Schlemm's canal. It belongs to the sclerotic and represents in a way a dissociated region of this membrane. Schlemm's canal communicates with and is a part of the venous system. In its structure it resembles the sinuses of the dura mater and might be called the scleral sinus. On the side of the anterior chamber it is covered by a system of trabeculae which may be intended to protect the absorbent surface of the canal from deposits of elements which otherwise might pass into the anterior chamber. The internal wall proper, however, is formed by a continuous membrane. The author does not believe in the existence of open communications between the anterior chamber and the canal of Schlemm, and therefore decides against the opinion that it corresponds to one of the lacunae of the sclero-corneal reticulum.

The Radical Operative Cure of Recent Traumatic and Myopic Detachment of the Retina.—Boucheron (*Archives d'ophthal.*, February, 1893) holds that every operation which evacuates the aqueous humor and keeps it evacuated, and which consequently produces a more or less persistent hypotonus in the anterior chamber, determines a dialytic current coming from the exudation accumulated outside the retina and the epithelial membrane of the flat zone of the detached processes, and coming also partially from the vitreous humor. The dialyzing membrane is formed by this fine epithelial membrane, consisting of a layer of cells and the hyaloid membrane. The greater the hypotonus in the exudation, the more powerful and rapid is the dialysis. When the eyeball is in a state of hypotonus the dialysis is slower and less complete. Hence operations for the relief of detached retina should be done during the brief period of hypertonus—that is, in the beginning or first stage. The object of such an operation should be to maintain a condition of hypotonus sufficiently prolonged either on the side of the anterior chamber or on the side of the sclerotic. The operation of iridectomy fulfils these conditions. The favorable cases occur in young subjects and before the sixth day of the existence of the detachment.

The Treatment of Strabismus by shortening the Straight Muscles.—Lagleyze (*Arch. d'ophthal.*, November, 1892) makes a vertical incision in the conjunctiva three millimetres from the corneal margin, and then excises a semilunar piece of conjunctiva. The conjunctiva is then dissected free from the muscle, and the external rectus from its anterior connection with the capsule of Tenon. The muscle is then separated freely from the underlying eyeball by two strabismus hooks. A suture

armed with two needles is then passed freely beneath the belly of the muscle. The upper needle is passed through the muscle from within outward near the upper border of the muscle, and the lower needle is passed in the same way through the muscle near its lower margin, and both needles are passed through the overlying conjunctiva. The loop thus made contains the fleshy portion of the muscle at a certain distance from the sclerotic tendon. The two ends of the suture are then turned toward the inner lip of the conjunctival wound. The upper needle passes beneath the conjunctiva and is brought out near the external and superior margin of the cornea, while the lower needle follows a similar course and is brought out near the infero-external margin of the cornea. The ends are then tied together and the muscle is thus folded forward on itself and by so much shortened.

Insufficiencies of the Oblique Muscles and how to Correct them.—Savage (*Ophth. Record*, July, 1892) believes that the cause of some cases of eye strain lies in a want of equilibrium of the oblique muscles. In detecting them, he places a modification of Maddox's prism before one eye, the other being covered, and asks the patient to look at a horizontal line on a card held eighteen inches distant. The effect of the double prism, so placed that the axis is vertical, is to make the line appear to be two lines, each parallel with the other. The other eye is then uncovered, and a third line is seen between the other two, with which it should be parallel. If there is a want of harmony on the part of the oblique muscles, this test will show it at once in a want of parallelism of the middle with the other two lines, the right end of the middle line pointing toward the bottom and the left end toward the top line, or *vice versa*, depending on the nature of the individual case. He always considers the eye before which no prism is held as the one under test. If the right ends of the middle and bottom lines converge while the left ends diverge, the superior oblique of the left eye is at once shown to be in a state of underaction. The function of the oblique muscles is to keep the naturally vertical meridians of the two corneas parallel even when not vertical. If there is perfect equilibrium of the obliques, this parallelism of the meridians named is maintained without trouble; but if the superior oblique of either eye is too strong for its inferior, or *vice versa*, the parallelism of the vertical meridians is preserved only by excessive work on the part of the weaker muscles, which will eventually bring on a train of nervous symptoms which seem incurable. In the treatment either concave or convex cylinders can be used; if the concave are used, and the insufficiency is in the superior obliques, the axes must be placed in the lower nasal quadrant; if in the inferior obliques, the axes must be placed in the lower temporal quadrant. If for the exercise the convex cylinders are chosen, the axes must be placed in the lower temporal quadrant for insufficiency of the superior obliques, and in the lower nasal quadrant for insufficiency of the inferior obliques. In either case the effect is increased as the axis is made to move from the vertical to the point of maximum effect, which is 45° from the vertical.

Heterophoria; a Safe Line drawn between Operative and Non-operative Cases.—Savage (*Ophth. Record*, January and February, 1892) draws the following conclusions: On the operative side of the line must be placed all cases in which the plane red glass produces diplopia. On the non-operative side should be placed, at least for a time, all cases of heterophoria in which diplopia is not induced by the plane red glass placed before one eye. Prisms, or decentered lenses, in position of rest, should always be resorted to primarily in all cases falling on the non-operative side of the line. There are cases, however, in which the use of prisms gives only temporary relief, and the strength must be increased from time to time until

finally the red glass again tried shows that the patient must be transferred to the operative side of the line.

A New Test for the Ocular Muscles.—Bumstead (*Annals of Ophth. and Otol.*, April, 1892) has devised an instrument for this purpose which consists of a half-cylinder of glass about three quarters of an inch long, which is fastened on a hard-rubber disc that is rimmed to fit the trial frame. The disc has a slit four millimetres wide, over which the segment of the cylinder is fastened. This constitutes a prism, or rather an innumerable series of prisms, which, instead of throwing one image on the retina of the eye before which it is placed, throws so many of them that, lapping as they do, they form a continuous band of light. If a candle is placed at twenty feet, or a small aperture in a black card before the window, and this instrument is held horizontally before one eye of the patient, a band of light will be thrown vertically on the retina, and will be projected outward to such an extent as to reach almost from the floor to the ceiling. If it is held before the right eye, and the band of light is to the right of the candle, esophoria exists for that distance, and in amount equal to the degree of the prism, base out, that is found necessary to make the band of light pass vertically through the candle flame. If it is to the left of the candle, exophoria is present, the extent to be determined as before, but with prism base in. When testing for possible hyperphoria, the half-cylinder must stand vertically before the eye, when the streak of light will run horizontally across the room, through the middle of the flame if there is equilibrium of these muscles. In this case also prisms held before the eye, base up or down, will measure the vertical aberration when it exists. For the near test with this instrument he uses a black line, between two and three millimetres in thickness and nearly five centimetres long, upon a white card. This is held vertically and opposite the meridian line between the two eyes, at the ordinary reading distance, and if there is equilibrium for this distance, the line is simply extended to the upper and lower borders of the card. If the muscles are not balanced, a second line will be seen either to the left or the right of the real one. Prisms, base in or out, will also give the degree of aberration at this point.

Glioma of the Optic Nerve; Exophthalmia; Enucleation; Death.—Keyser (*Annals of Ophth. and Otol.*, October, 1892) reports an interesting case occurring in a child aged eight years. When he saw the child the right eye was very protuberant and its movements restricted. Tension was +2 and vision was nil. The ball could not be pushed back into the orbit, and a thick, hard mass could be felt behind the ball. There was not much pain. The eye was enucleated, and the optic nerve was found very much enlarged and was severed half an inch in front of the foramen. Five days later the patient vomited, and the temperature rose to 103.4° , with slight delirium, which increased. On the eighth day the right side of the face, right arm, and right leg became paralyzed, coma set in, and death occurred on the tenth day. At the autopsy there was found a general meningitis of the brain, with considerable pus. The right optic nerve was markedly swollen. On the left optic nerve, external to the chiasm, there was a globular tumor three quarters of an inch in diameter, and another small growth sprang from the base near the pons on the right side. In the white substance of the left middle lobe, anterior to the lateral ventricle, was a cyst $1\frac{1}{2} \times 1 \times 1$ inch with amber-colored fluid contents. Both tumors springing from and involving the left optic nerve, on being microscopically examined, proved to be true glioma.

Blood Effusions between the Retina and the Vitreous Body.—Hotz (*Annals of Ophth. and Otol.*, January, 1893) reports three cases of this nature, in all of which the similarity

of symptoms was striking. Sight was suddenly reduced to perception of light, which appeared colored as if seen through a brown or reddish medium. The ophthalmoscope showed a large effusion of blood in the region of the macula, and reaching close to the temporal border of the papilla. The blood was absorbed in the course of four weeks or more, and no trace of any lesion could be found in the fundus. The perfect recovery of vision is the strongest argument against the assumption of the blood effusion being into the substance of the retina, the structure of the macula not being disturbed in the least.

The Clinical History of Central Circumscribed Chorioretinitis.—Gradle (*Annals of Ophthalm. and Otol.*, January, 1893) considers that this disease is evidently localized in the chorioid, as indicated by the general uveal irritation and subsequent pigmentary changes. The interference with vision shows that the external layers of the retina are also involved. The glistening of the recent "plaques" suggests a disturbed state of the membrana limitans. The limitation of the inflammatory process to a circumscribed area of the fundus, with disturbance of nutrition in the uveal tract and the vitreous, points to an infectious origin of the disease, the infectious material probably entering by way of the short posterior ciliary arteries.

The Ripening of Immature Cataracts by Direct Trituration.—Bettmann (*Annals of Ophthalm. and Otol.*, January, 1893), in order to avoid an unnecessary rubbing of the cornea and squeezing of the iris, and to prevent an unwarrantable mutilation of the latter by iridectomy, advises an incision in the sclero-corneal margin and the insertion of a trowel-shaped spatula. The flattened end of this instrument is placed on the lens surface within the pupillary space. If the pupillary field is small, it is slid beneath the iris below and on either side, and the lens is then subjected to trituration. If the cataract is of the soft variety, the cortex may be seen to break down while being manipulated. The construction of the trowel spatula prevents contact with the iris, the shank being in a higher plane than the iris.

The Use of Thiersch's Skin Grafts as a Substitute for Conjunctiva.—Hotz (*Annals of Ophthalm. and Otol.*, April, 1893) takes his grafts from any convenient surface of the skin as follows: The skin is rendered thoroughly aseptic, and then, being drawn tense and well wet with a one-half-per-cent. solution of sodium chloride, the blade of a sharp razor is laid upon it and firmly pressed against the skin in such a manner that slight sawing motions will make the edge of the razor just cut down to the papillary layer and shave off a thin scale, consisting of epidermis and the tips of the papillæ. The transplantation of these slips upon a wound is a simple procedure and usually crowned with success. He advises their use in four classes of cases: 1. For the relief of extensive adhesion of the lower lid to the eyeball, following the destruction of the palpebral and ocular conjunctiva by lime or hot metal. 2. For the relief of excessive shrinkage of the conjunctiva in trachomatous eyes. 3. For enlarging a contracted conjunctival pocket to make the insertion of an artificial eye possible. 4. In certain cases of pterygium.

The Diplometer.—Galezowski (*Rec. d'ophthal.*, March, 1893) here describes an instrument which consists of a box like a stereoscope, which serves as a dark chamber. At the back part are placed two peep-holes. In front of each of these holes is a metallic disc armed with a double groove for the reception of correcting glasses for distant vision and of a red glass. The front part of the box, much larger than the back, is closed by a ground glass, divided horizontally and vertically by lines. Each vertical line is numbered to the right and left of the median line, while the horizontal lines are represented by letters. One metre from the peep-holes stands a vertical rod, the top

of which corresponds to the center of the ground glass, on which is placed a lamp which glides smoothly along a metric measure. The latter turns around its point of fixation and describes a circle parallel to the surface of the ground glass. The lamp is mounted in such manner as to follow all the rotary movements of the metric measure or rule, always, however, maintaining its vertical position.

The Variations induced by Advancing Age in the Radii of Curvature of the Lens.—Bertin-Sans (*Archives d'ophthal.*, April, 1893) concludes from his observations that the radii of curvature of both surfaces of the lens accommodated for the remote point increase as the animal grows older, and the same holds true of man. These conclusions agree perfectly with our knowledge of the development of the lens, which maintains the same thickness, according to Sappey, throughout its entire existence, and only grows by elongation of its diameter by the addition of new fibers.

Skiascopy.—Hess (*Kl. Mon.-f. Aug.*, May, 1893) has devised an instrument for practicing skiascopy, for which he claims the following advantages: 1. The distance at which the observer carries on his investigations remains always the same, and the size of the field of illumination remains also the same. 2. By the great distance of a hundred and twenty centimetres employed, slight deviations from the middle distance exert no effect on the result. 3. The change in the glasses is made more rapidly and surely than in any other way, and at the same time their distance from the eye is not changed.

The Spectroscopic Analysis of a Black Cataract.—Gillet de Grandmont (*Archives d'ophthal.*, May, 1893) concludes from his investigations that the color of black cataracts is due to the coloring matter of the blood transformed into precipitated hæmatin. It differs from the pigmentation of the chorioid, and is not due to melanin. The coloring occurs by progressive imbibition, the parts nearest the capsule being the most deeply colored.

The Perimetry of Colors.—Hegg (*Ann. d'oc.*, May, 1893) draws the following conclusions: 1. The perimetry of colors is not the equivalent of the determination of the peripheral sensibility of the retina for colors, because this determination only permits a single intensity of irritation. 2. Nevertheless, different colors constitute irritations of different intensity, and each color taken alone represents at the extreme limit of the points of the retina which still perceive it the minimum of irritation for these points. 3. The sensibility of the retina for colors diminishes progressively from the center toward the periphery. 4. The cause of this diminution of sensibility toward the periphery must probably be sought for in the sensory elements of the retina itself. 5. In the lesions of the optic nerve, we may formulate a conclusion as to the eccentric visual acuity, based on the manner in which the colored visual fields act, but only when the refractive media project a well-defined image on the retina. 6. The perimetry of the colors enables us to judge in all cases of the continuity of the visual field. 7. All colors may be divided into two groups: (1) Those which at the periphery pass through the blue to neutral gray; (2) those which at the periphery pass through yellow to neutral gray. 8. All colors hitherto employed for perimetric purposes vary both in tint and saturation as we go from center toward periphery. Hence they can not be utilized. 9. Invariable or unchangeable colors are those which vary in saturation but not in tint, proceeding from center toward periphery. 10. These unchangeable colors may be rendered equivalent in pairs, and to all may be given the same white value. 11. The visual field of red is equal to that of green; that of blue is equal to that of yellow. 12. Researches into the domain of the perimetry of colors can not pretend to any scientific value, unless made with unchange-

able colors of the same white value. 13. With these pigments a patient can not determine accurately its color.

Excision of Orbital or Palpebral Lacrymal Glands in Simple or Complicated Rebellious Lacrymation.—Truc (*Archives Ophthalm.*, May, 1893) draws the following conclusions from his observations: Excision of the lacrymal gland is an operation which may be employed in the treatment of simple or complex obstinate lacrymation as a means of last resort. Excision of the palpebral gland is to be preferred for the simple cases. Excision of the orbital gland may be employed in cases of granulations, where the conjunctival *cul-de-sac* is much altered, destroyed, or densely infiltrated. It is useful in certain cases of severe chronic blepharitis with hypertrophy of the mucous membrane and marked ectropium.

Temporal Hemianopsia with Recovery, followed by Right Lateral Hemianopsia, Ophthalmoplegia, and Partial Recovery.—Würdemann and Barnes (*Arch. of Ophthalm.*, xxii, 2) report in full this very interesting case. The original lesion was believed to have been miliary aneurysms at the base of the brain, due to an atheromatous condition of the vessels engendered by years of general anæmia. The first apoplectic attack was apparently due to a circumscribed hæmorrhage at the anterior portion of the optic chiasm pressing upon the decussating fibers, thereby producing temporal hemianopsia, the clot afterward being absorbed, but not before pressure on the optic nerve, resulting in partial atrophy, had occurred. The almost complete restoration of the visual fields under treatment is unusual. The erratic changes in the visual fields with the paræsthesia and mental disturbance that followed were not recognized at the time as prodromata of a second attack, the cause of which was probably debility resulting from dysentery. At this time the hæmorrhage was more posterior, involving the whole of the left optic tract, and for a short time affecting the third nerve of the same side, as is shown by the evanescent external squint and ptosis. No explanation of the peculiar changes in central vision and of the condition of the color fields is offered.

Ophthalmia Nodosa caused by a Penetrating Caterpillar Hair.—Krüger (*Arch. of Ophthalm.*, xxii, 2) reports four cases of this rather rare disease. He considers that the protracted affection with formation of nodules is very rare. The chief danger rests in the complication of iritis. The structures of the hairs, chiefly the little hooks, enable them to penetrate so far into the membranes of the eye, especially if favored by the patient rubbing the eye. The diagnosis will not be difficult if conjunctival nodules or free hairs are present, as such multiple tough nodules persisting very long without decay do not occur in general affections, nor in connection with other foreign bodies. In those cases in which the iris alone shows nodules the diagnosis is only possible after excision of the piece of iris with the nodule. The prognosis must be guarded on account of the complicating irido-cyclitis, which may lead to occlusion and seclusion of the pupil.

The Pathology and Pathogenesis of Retinitis Proliferans.—Bauholzer (*Arch. of Ophthalm.*, xxii, 2) believes that many of the large vessels reported as seen in many cases of retinitis proliferans owe their visibility to the detachment of the retina, and are not new-formed vessels. Whether the retinal proliferation is primary and the involvement of the vitreous secondary, can not be definitely decided. We find, however, parts with excessive proliferation of the supporting tissue without deposits on the side of the vitreous. Whether the detachment of the limitans interna favors the proliferation of the supporting fibers is doubtful, since the proliferation is found where the limitans interna is normal. Intra-ocular hæmorrhage stands in intimate causal relation with the proliferation. In

most of the cases published there was intra-ocular hæmorrhage, either in the vitreous or retina. The fairly good vision which is sometimes found, even late in the disease, finds its explanation in the fact that the nervous elements, particularly the rods and cones, are relatively intact.

Miscellany.

Ferratin.—This is the name given by Professor Schmiedeberg, of Strassburg, to a compound of iron which he has extracted from the liver of the hog. Ordinarily, he says, it contains six per cent. of iron. As now prepared, and to be obtained in commerce, it occurs in the form of a fine powder of a reddish-brown color, of two varieties, one of which is insoluble, and the other, combined with sodium, easily soluble in water on agitation. For the purpose of dissolving the second form of the powder the water must be as free as possible from lime, otherwise an insoluble calcium ferratin will be formed. A watery solution of the sodium compound may be added to milk or to any other liquid food, especially in the diet of little children. Either form of ferratin may be administered in the shape of powder. From a grain and a half to seven grains may be given daily to children, and from fifteen to twenty-two grains to adults. It may be given in one dose or in two or three doses. Acid articles of food should not be taken during the employment of ferratin.

Desternalization of the Ribs.—In *La Province médicale* for November 4th there is an article by Dr. Jaboulay, surgeon to the Hôtel-Dieu of Lyons, on the subject of desternalization of the ribs and its employment in the treatment of large purulent accumulations in the pleura and in that of scoliosis. When, he says, in the dead body the costal cartilages are detached from the sternum, or when they are simply cut through at about their middle from the first to the seventh, the side of the chest wall corresponding to the divided costal cartilages will be seen to become flattened, especially behind, and to become contracted transversely, the ribs tending to the median line and in from of the sternum. This change in the shape of the chest is still more evident when the corpse is placed in a sitting posture. If it is stretched out on the back, the weight of the upper limbs, through the medium of the clavicles, drags the first and second ribs away from the median line instead of allowing them to approach it as all the other ribs do. The same change takes place on both sides. If bilateral desternalization is practiced, or if the sternum is removed, the chest becomes narrowed transversely to an extent equal to the whole breadth of the sternum, or even a greater extent. It will be understood that by means of this double measure one may contract the thorax almost at will by adding transverse compression to the narrowing set up by this operative procedure. These effects may be made use of in the treatment of purulent pleurisy when it is not cured by puncture and by the ordinary operation for empyema. Unilateral or bilateral desternalization or resection of the sternum seems preferable to the resection of a great number of ribs, as the latter procedure in severe and inveterate cases is not likely to prove successful. The author insists upon this point, that when a rib is removed the transverse sinking of the chest wall affects only the level of that rib and a portion of the intercostal spaces above and below it, and diminishes at the same time the height of the side of the chest, so that, in order to completely efface one side of the chest, as is commonly necessary in cases of enormous effusion, it would be necessary to

remove all the ribs. Desternalization, on the contrary, affects all the true ribs, and makes the corresponding half of the chest entirely mobile.

A Medical Line Officer of the Russian Navy.—The *Nouvelles Montpellièr médical* for November 4th contains a paragraph concerning a Franco-Russian medical banquet lately given in Paris, at which the representative of that journal fell in with Dr. Botkin, the son of the celebrated professor, who, at the conclusion of the regular toasts, rose to drink to France. The account mentions the great stature and elegant appearance of this young man, who is undoubtedly remembered most pleasantly by many New York physicians who had the privilege of making his acquaintance when the Russian men-of-war were anchored in the North River last spring. It seems from the article given in our contemporary that, besides being a naval surgeon, Dr. Botkin is a line officer of the rank of ensign, and it is said that his reason for assuming the double character was to enable him to add military discipline to the moral influence of the physician, both of which he might have occasion for in certain explorations in Central Asia that he had in view.

Guaiaol in the Treatment of Erysipelas of the Face.—In the *Lyon médical* for November 5th, Dr. L. Bard publishes the conclusion of an article giving his experience in the treatment of erysipelas of the face by painting with guaiaol. He relates five cases, all of which ended in recovery. Undoubtedly, he says, the prognosis of erysipelas of the face is not very grave, and recovery is the most frequent termination; nevertheless the mortality in severe cases is far from trifling, and four of the cases related had, before the application of the remedy, manifested a gravity above the average. In three of them there was albumin in the urine, and all four of the patients had prolonged delirium. In two cases the symptoms were particularly alarming and included a condition closely bordering on coma. In every case the disappearance of the fever was hastened by the use of the remedy. As regards the theory of the antipyretic action of guaiaol applied to the skin, the author is inclined to accept that of its action on the nervous centers, but without committing himself as to the precise mechanism of that action. Whether the drug acts by being absorbed, or acts upon the peripheral nerves, it is probable that at the same time it exerts upon the thermic centers a moderating or anæsthetic influence and has a peripheral vasomotor action more or less closely allied to the former.

Phosphorus in the Treatment of Rickets.—Dr. Louis Guion contributes to the November number of the *Revue mensuelle des maladies de l'enfance* a description of the method by which Dr. Oscar Rie, of Vienna, employs phosphorus in the treatment of rickets in Dr. Kassowitz's service in a public institute for sick children. The simplest formula and the least costly, such as may be used in a hospital, is a solution of one part of phosphorus in ten thousand parts of cod-liver oil, of which a teaspoonful is to be taken once a day. As the pharmacists can hardly weigh so small a quantity of phosphorus, Dr. Kassowitz suggests that a concentrated mother solution of phosphorus in oil of sweet almonds, in the proportion of one to five hundred, be kept on hand. Five grammes of this solution, containing 0.01 of a centigramme of phosphorus, would form with ninety-five grammes of cod-liver oil the one-to-ten-thousand solution. If the child can not or will not take it, the following formula may be tried: One centigramme of phosphorus, one hundred grammes of cod-liver oil, five grammes of saccharin, and eleven drops of essence of lemon; a teaspoonful to be taken daily. If this form is not acceptable to the child, Kassowitz prescribes a mixture of one centigramme of phosphorus

thirty grammes of lipanin, fifteen grammes each of white sugar and gum arabic, and forty grammes of distilled water; a teaspoonful to be taken daily. Another is this: One centigramme of phosphorus and five grammes each of lipanin and olive oil; ten drops to be taken daily. The use of any of these preparations may be continued for months at a time.

There are numerous and decided partisans of this treatment, and it also has staunch adversaries. The latter maintain either that it is insufficient and needs to be re-enforced by all the ordinary hygienic rules, or that its action is solely that of the cod-liver oil. M. Guinon endeavored to test its efficacy in Professor Grancher's service in the year 1891 to 1892, and used the one-to-ten-thousand oily solution of phosphorus. The trials were made on forty-one children ranging from a few months to three years in age. Unfortunately, although the medicine was dispensed gratuitously, most of the patients could only be kept sight of for a very short time, because they did not return. Thus, twelve of the children did not reappear and four took the oil only fifteen days; so that there remained twenty-four children treated from a month to six months. This period is rather short for the observation of modification in the bones, but the parents' negligence and their final disappearance prevented a longer continuance; nevertheless, the treatment gave results constant enough to convince M. Guinon. In the first place, the oil was generally well borne. Sometimes in children whose digestion was already disordered it provoked transitory disturbances which ceased spontaneously. In five cases the author observed vomiting for a day or two. In one case there was a saburral state, which was of brief duration, and in three cases there was a little diarrhoea; but the children rapidly became accustomed to the remedy and succeeded in digesting it well. In no instance was poisoning observed. In one case, by mistake, the mother gave two dessertspoonfuls for two or three days. The child, who was twenty-two months old, merely had some abdominal pains with constipation.

If we are to form a sound judgment, the author says, of the effects of a treatment in rickets we must not, as is too often done, limit our observation to the condition of the osseous system. There, it is true, is the most prominent phenomenon, but it is only a small part of the symptomatology. Other disorders must be taken into account—namely, the dentition; the state of the digestive organs, as to constipation, diarrhoea, and vomiting; general and localized convulsions, and spasm of the glottis; cough, simple or accompanied by sibilant bronchitis; sweating of the head, a phenomenon that is common and that so often precedes deformities; the pains that are so frequently manifested when the child is taken under the arms or lifted by the arms, and when it is placed on the floor; the ordinary apathy of rachitism; the difficulty or impossibility of walking and of maintaining the erect posture; the weight and the mien, and finally the enlargement of the liver and of the spleen, which latter phenomenon the author has found to be relatively rare in his observation. Taking all these elements into account, he has been struck with the rapid improvement in the majority of cases. Generally at the end of fifteen days the mother reported that the child was more cheerful, that he coughed less, that his digestion was better, and that sometimes he slept better. At the end of from three to four weeks the mother would remark that instead of lying stretched out and flaccid, if it was a nursing, the child would sit by itself or try to do so. If it was an older child, instead of remaining seated it would stand or try to do so. Finally, at a more advanced age it would try to walk, or begin to walk if it had lost the ability to do so, as so often happens in rickets during the second year of life. At the end of two months or more it is observed that the teeth make their appearance, although retarded,

but on this point the author's conviction is less positive, for it is difficult in such a case to appreciate the effects of the treatment. In only two cases has he noted changes in the condition of the bones, the epiphyses having diminished in volume and the curves having been altered. He admits, however, that the period over which his observations extend was not sufficient to allow of appreciating an amelioration necessarily very slow. Yet it may be said that the progress made in walking and standing was a sufficient proof, and the author is quite ready to believe that it was the effect of an increase of muscular force, as was proved by the firm consistence of the flesh, the greater vivacity, and the improved color.

He thinks that salt baths, frequent general friction, the open air, and a carefully regulated diet have a very favorable and prompt effect in rickets, and should always be resorted to in conjunction with the use of the phosphorized oil. This practice, he thinks, should always be adopted when it is impracticable to prescribe a sojourn at the seaside.

The Topical Use of Salicylic Acid in the Treatment of Acute Articular Rheumatism.—In the *Revue générale de médecine, de chirurgie et d'obstétrique* for November 8th we find an abstract of an article on this subject by M. Bourget, published in the *Revue médicale de la Suisse romande*. The article concludes as follows: 1. The absorption of salicylic acid by the skin is rapid and very energetic. In young subjects the absorbent power of the skin is greater than in old persons, and the skin of blondes seems more permeable than that of individuals whose hair is black and whose skin is swarthy. 2. The rapidity and intensity of this cutaneous absorption always depends upon the vehicle employed to dissolve the salicylic acid. Fatty bodies are the only ones that allow of a higher degree of penetration through the skin, while with vaseline and glycerin it is far less active if it occurs at all. 3. The treatment of acute articular rheumatism with a salicylized terebinthinate ointment is very much to be recommended. 4. This ointment is less efficacious in other forms of rheumatism, but it may be used as an adjuvant to massage. 5. It has no effect in gonorrhœal rheumatism.

The Predisposing Causes of Retention of Bile in the Gall Bladder.—In the concluding portion of an article entitled *Some Observations on the Pathology, Ætiology, and Treatment of Gallstones*, by Dr. E. M. Brockbank, of Manchester, England, published in the November number of the *Medical Chronicle*, attention is given to the causes which predispose to the retention of bile in the gall bladder. The first one considered is the dependent position of the fundus of the gall bladder. If, says the author, a normal gall bladder and liver are examined—and this is best done on a model taken from a frozen normal liver, such as is used for teaching purposes in the anatomical lecture room—it will be found that the fundus is distinctly at a lower level than the termination of the cystic duct at its junction with the hepatic duct. As the gall bladder is directly apposed to the lower surface of the right lobe of the liver, it follows the direction taken by the anterior margin of the lobe as it curves down to the costal arch. The fundus is movable, and is always the most dependent part, while the cystic duct remains fixed at the hilum of the liver. The line drawn through the long axis of the gall bladder, passing through the cystic duct at its junction with the hepatic duct and through the fundus, will be found to be oblique, running forward and downward, and the difference of level at the two extremities, when the normal gall bladder is in a state of medium distention, will be about an inch. This difference in level can easily be seen in the post-mortem room, where it will very often be found to be much increased, especially if the gall bladder is distended.

Any causes that depress the anterior portion of the right lobe of the liver will tend to increase the obliquity of the longitudinal axis. The wearing of a tight corset is an example of such a cause, as it produces a marked groove in the right lobe and depresses it greatly at the same time. The German pathologists term this altered liver *Schnürleber*, and mention it as probably the exciting cause of gallstones. The consequence of all this is that even under normal conditions the gall bladder has to be emptied against the action of gravity, so that there is a tendency for it to be emptied only incompletely, and this would be more decided where the bile was thickened or contained a sediment. This dependent position of the fundus of the gall bladder, the author says, is much more marked in quadrupeds than in man, and the long axis is almost vertical. When the animal lies on its side the gall bladder is in a much better position to discharge its contents. Can this, the author asks, be a reason why animals, especially dogs, generally lie on the side after a heavy meal? In man the posture of leaning forward adopted at the writing table would tend to bring the gall bladder more toward the quadruped position and increase the difficulty of emptying it, and an easy-chair position would act in the opposite direction. The author then considers the relation of the hepatic flexure of the colon to the gall bladder. The flexure, he says, is in immediate apposition to the gall bladder and to the cystic duct, and feces collecting here, as they tend to do, at both flexures of the colon in chronic constipation, which occurs so often in women, would interfere with the complete discharge of bile from the gall bladder.

Uræmia as a Sequel of Measles.—Dr. S. Zichy-Woinarski reports in the October number of the *Australasian Medical Gazette* a case of measles followed by fatal uræmia. He speaks of the extreme rarity of fatal uræmia as a complication or sequel of measles, but states that two other cases have occurred during the present epidemic of measles in Ballarat. One was in a girl six years old. The renal condition was diagnosed as one of acute desquamative nephritis, and the author asks if it might not be that in this case the morbid matter expended most of its violence on the hypoblastic tissues in place of the epiblastic, the ordinary field of its intense action.

The Hypodermic Use of Aristol.—Aristol, or biniodized thymol, or biniodide of dithymol, remarks a writer in the *Progress médical* for November 4th, is a substance that was obtained by Messinger and Wartmann by the action of a solution of iodine and iodide of potassium on a solution of thymol in caustic soda. It is described as an amorphous powder of a brick-red color and tasteless, having a slight odor of iodine and of thymol. It is insoluble in water, slightly soluble in alcohol, and freely soluble in ether, in sulphide of carbon, and in the fixed oils. On exposure to air and light it loses a part of its iodine. It was employed by Erchoff and Raymond as a substitute for iodoform. Brocq recommended it in powder or in ointment in diseases of the skin. Vinay employed it in gynecology and as a remedy for excoriation of the nipples, and Huchard used it internally in pulmonary gangrene and tuberculosis, in doses of from four to six grains daily, in pills of a grain and a half each.

Hypodermic injections of aristol dissolved in oil of sweet almonds have been used by Nadaud as a remedy in pulmonary tuberculosis. He injects at first one cubic centimetre, and then from two to three cubic centimetres of a 1-to-10,000 solution of aristol in oil of sweet almonds. These injections are not painful, and if ordinary antiseptic precautions are taken they never cause abscess. Nadaud has observed that this treatment causes a general amelioration of the symptoms of tuberculosis—such as cough, sweating, and difficulty of breathing.

The Dangers of Overfeeding in Children.—The *Mercredi médical* for November 8th summarizes a recent thesis by Dr. Paul Bellot in which the author calls attention to the frequency of disturbances due to overfeeding, not only in infants at the breast, but also in those who are older and take ordinary food. He has made a study of these disturbances as they affect the digestive canal, the liver and the kidneys, the locomotor apparatus, the skin, and the nervous system. It is not sufficiently recognized, he says, that hepatic colic is apt to attack overfed children, especially those who live in cities and therefore lead a sedentary life not very favorable to the combustion of fatty food. Although less frequent than in adults, hepatic colic is not positively rare in children. Rousson found concretions in the biliary passages of the new-born, and Hein observed hepatic colic in a child twenty-five days old. Undoubtedly heredity and a sedentary life may of themselves play an important part in the ætiology of this morbid assemblage of symptoms, but it is not the less true that it is in a measure to be imputed to overfeeding. By causing congestion of the liver this sets up inflammation of the biliary passages. It follows that the mucus secreted by the glands of these canals acquires an acid reaction and decomposes the biliary acids, which then lose their solvent power and allow pigment and cholesterol to be deposited in the form of small concretions, or biliary sand, the starting point of calculi. Cases of this kind are not rare, and M. Bellot cites one that is very striking.

In common with hepatic colic, nephritic colic is not very rare in children during the second infancy, or even during the period of nursing. Sometimes the new-born present uric-acid infarctions in the canals of Bellini, in the calices, and in the pelvis of the kidneys. The origin of this renal lithiasis before birth is rather obscure, but the diet of the mother and hereditary influences may be considered to play an important part. During lactation overfeeding may be a cause of disease. In the second period of infancy authors commonly recognize the influence of excessive feeding and of a diet containing too much animal food. Similar affections, as Bouley has shown, occur in young animals. As regards the skin, the correlation existing between various skin diseases and gastro-intestinal derangements in children is indisputable, and these gastro-intestinal troubles are very often due to overfeeding, which therefore should be considered as very commonly the primary cause of these different cutaneous affections. According to Brocq, symptomatic skin diseases may be the result of accidental poisoning by drugs, articles of food, or a morbid toxin; or of an organic disease acting in a reflex way; or of progressive vitiation of the general condition; or of defective nutritive exchanges. In the case of overfed nurslings, the first and second of these ætiological factors do not generally play a part, unless the milk on which the children are maintained is of an extremely bad quality, but the same is not true of an organic lesion acting in a reflex way, or of the imperfect nutritive exchanges which undermine the vitality of an organ and make it morbidly vulnerable. In the case of infants subjected to a mixed diet or to a diet containing no milk all four of these causes may come into play.

As regards the genesis of certain skin diseases, such as urticaria, following the abuse of drink, and often observed in persons with dilated stomachs, a reflex action upon the cutaneous vaso-motor nerves must be admitted or, in a weaned child, a direct action of ptomaines taken in excess into the system with articles of food. In other cases, on the contrary, and these are the commonest, where it is a matter, for instance, of impetiginous eczema, or seborrhoeic eczema, or eethyma, or different forms of acne, strophulus, etc., the pathogeny is probably different, in that case involving the direct elimination by the sweat glands of volatile fatty acids which, in their passage through

the skin, alter the anatomical elements of the integument. Among these various skin diseases there is one—eczema seborrhoeicum of the hairy scalp and of the face—that is observed in large, fat children, who assimilate the great quantity of food which they take—that is to say, who bear overfeeding without gastro-intestinal troubles. One point it is very important to recognize—namely, that digestive derangement is not at all necessary to the production of skin diseases in an overfleshy or overfed child. In all these conditions it is a prime requisite of treatment to reduce the amount of food taken.

Ergotine Gallate as a Hæmostatic.—The *Deutsche Medizinisch-Zeitung* cites from the *Deutsche medicinische Wochenschrift* a formula employed by Dr. Blaschko, of Berlin, in hæmoptysis. The formula calls for a solution of one part each of gallic acid and ergotine in a mixture of twenty-five parts each of distilled water and syrup of althæa, of which a teaspoonful is to be taken every two hours. The author has observed admirable results from the use of this agent. Where there is much disposition to cough, the syrup of althæa is replaced by syrup of diacodium, and, if there is imminent danger of death, the patient takes the teaspoonful every hour.

The late Dr. John C. Peters.—At a meeting of the New York Academy of Medicine held on November 2d the following resolutions were adopted:

Resolved, That there be spread upon the minutes of this meeting the following as a brief expression by the Academy of its appreciation of the character and professional merit of John Charles Peters, M. D., whose death has recently been announced.

During a long life of professional activity he gave generously of money, time, and effort toward the promotion of science, the welfare of the profession and community, and the interests of the Academy. As an author and bibliophile he was eminent. He was foremost in the foundation of the New York Pathological Society and contributed greatly to its successful development.

His studies of Asiatic cholera are recognized as most important contributions to the knowledge of the profession, both here and abroad, and his generous gift of the literature of this subject forms one of the most complete departments of our library.

The incomplete list of nearly thirty titles of his works given in the *Index Catalogue* of the surgeon general's office, a larger part of which relate to elaborate treatises, illustrates his activity as a writer and the comprehensive character of his writings.

The *Medical Gazette*, the *Transactions* of the New York Pathological Society and the *Academy* are some of the evidences of his rare editorial ability.

The numerous positions of honor and trust to which he was elected in the many organizations of which he was a member, evince the confidence of his associates and his remarkable executive skill.

Few matters relating to public sanitation failed to elicit his active support, and his communications through the secular press, whether anonymous or with his name, were of great influence in directing public and legislative action.

His intelligent supervision of our library and his influence with others were the cause of much of its subsequent prosperity.

His keen sense of personal dignity and probity made his example and precept respected by all who knew him, and his genial temper, kindly humor, and modest avoidance of anything that might be regarded as obtrusive have endeared him to all his associates.

The Academy was ever honored by his fellowship, and his friends were always the gainers in their relations with him.

Original Communications.

SURGICAL SHOCK.*

By CHARLES P. NOBLE, M.D.

SURGEON IN CHIEF OF THE KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

It is proposed in this communication to briefly consider the nature of surgical shock, and then to take up its treatment in detail. Shock is a condition of the body which is characterized by feebleness and rapidity of action of the heart, by the shallowness and frequency of respiration, by the lowering of the temperature of the body, and by the lessened activity of most of its functions. Intellection, digestion, and the secretion of urine, all are more or less in abeyance. It is probable, also, that the processes of assimilation and metabolism are profoundly interfered with. Perspiration is usually free, the body being covered with a cold, clammy sweat. This, however, is due not to the increased activity of the sweat glands, but rather to an arrest of the activity of their cells, so that they simply act as strainers for the watery part of the blood to pass through them.

There can be no question that vitality is at a low ebb when shock exists, but there is some difference of opinion as to the real physiology or pathology involved. It is generally accepted that shock is a manifestation of paresis of the nervous system, its symptoms being due to lessened and irregular innervation. The question as to whether the cerebro-spinal or the sympathetic system is most involved is in dispute, and we do not propose at this time to attempt the elucidation of the question. As a matter of fact, injury of the body in any of its parts can bring about shock. Injuries to certain parts of the body are especially apt to produce shock. These parts are the testicle and urethra in the male, the ovary (in a lessened degree) in the female, and the abdominal viscera. Examples of shock from injury to these structures are common and familiar to every one of experience. The familiar experiment of temporarily arresting the heart's action of the frog by a blow upon its abdomen is a striking illustration. Leaving aside the disputed points at issue, we wish to consider certain facts because of their very practical bearing upon the therapeutics of surgical shock. Among the most important symptoms of shock is the lessened force and greater frequency of the heart's beat. The activity of the respiratory center also is much lessened. The superficial blood-vessels are contracted, so that the surface of the body is pale and even blanched. The temperature of the body is lowered below the normal. These facts are indisputable, and a recognition of the existence of these conditions forms the basis for rational therapeutics. Heat must be restored to the body; the heart and respiratory centers must be stimulated to do their work; and the superficial blood-vessels must be dilated, so that the circulation may be equalized,

by affording a channel for the blood which has been retained in the great veins of the abdomen. The practice which I have followed for some years to accomplish these results will now be given.

Treatment of Shock.—The most important point in the treatment of shock is its prevention. Much can be done by prudent management either to avoid shock or to lessen its degree. In selecting the date for operation a time should be chosen when the patient is in good condition. Almost always this is possible. It is only in emergency cases, and when patients are suffering from a disease whose progress is steadily and rapidly downward, that preparatory treatment will not put them in better condition. All patients requiring operation should receive careful study, and every therapeutic indication should be met before operation. Especially should the condition of the emunctories be looked after. The bowels, skin, and kidneys should be put in good condition by the use of baths, purgatives (especially broken doses of calomel and salines), and the abundant ingestion of water. The *morale* of the patient should not be neglected, as much can be done, by stimulating the courage of the timid and allaying the fears of the despondent, to make the patient look forward to her operation with courage and without dread. All these matters should be attended to prior to the day of operation. The temperature of the room in which the operation is done should be high—from 75° to 85° F. In such a room the loss of heat from the patient by radiation is much less than when the operation is done in a cool room. Loss of heat from the patient can be lessened also by the manner in which she is dressed. It is best that she be well wrapped in blankets, and that as little of the skin surface be exposed to the air as the necessities of the particular operation permit. For the same reason the use of *wet* towels or gauze about the patient is to be deprecated. Evaporation from such wet materials chills the patient. Much can be done also by the proper administration of the anæsthetic. Patients should not be drowned in ether. Enough only should be given to maintain anæsthesia, unless, to meet a certain indication, absolute relaxation is required. The prevention of hæmorrhage and the avoidance of rough handling of the patient, especially of the abdominal viscera, are matters of the greatest importance in preventing shock. The careful surgeon gives due attention to each and all of these matters of detail, and no one so much appreciates their importance as he who has to deal constantly with grave operations. This applies especially to the abdominal surgeon, because, in many cases, when he begins an operation the life of the patient depends upon its completion. He can not do a part of it and postpone the rest to another day. In many of the long, tedious operations which he is called upon to do, involving multiple visceral adhesions, the very life of the patient itself depends upon attention to every detail to prevent shock, so that he may have time to complete the operation *secundum artem*.

The active treatment of shock consists in supplying to the body heat which has been lost, in stimulating the heart to better work, in counteracting nervous depression,

* Read before the Obstetrical Society of Philadelphia, December 7, 1893.

and in overcoming irregular action, especially on the part of the vaso-motor nervous system, until reaction shall occur and the vitality of the patient can be sustained by alimentation. In describing the treatment of shock I shall simply give an account of my own practice in the treatment of this condition.

If during the operation the patient begins to suffer from shock and there is reason to expect that this will increase, especially if the operation is not yet completed, I begin at once actively to treat it. A fifteenth of a grain of sulphate of strychnine and a fiftieth of a grain of digitaline is given hypodermically, and the dose of strychnine is repeated every fifteen minutes until some improvement is manifested in the pulse or a fifth of a grain has been given. If improvement does not manifest itself promptly, and especially if shock be profound, or if the patient has been markedly prostrated before the operation, a hundredth of a grain of atropine sulphate and two or three minims of a one-per-cent. aqueous solution of nitroglycerin are given hypodermically. In still other cases from three to six grains of citrate of caffeine are administered in addition. During this time hot-water bottles have been put about the patient, and if the operation is an abdominal section, at times warm water is poured into the peritoneal cavity. I have also employed hot beef-tea enemas, but, as a rule, an enema is not given, because it interferes with the completion of the operation, which is just as important as any one detail in the treatment of shock, if not more so. In fact, it is of the highest importance to complete the operation as rapidly as is consistent with safe work. The same is true of the after-dressing of the patient, who should be put to bed as promptly as is feasible.

The bed should have been warmed by having hot-water bottles in it while the operation was in progress, and in all cases in which shock is a marked feature the sheets should be removed and the patient placed between warm, dry blankets. At this stage the use of whisky by enema is of service, and at times it is proper to use whisky during the operation, especially if shock is not another name for too much ether. The use of whisky or alcohol in any shape is not good treatment for an overdose of ether. The best way to employ whisky, as a rule, is to give it by enema with hot beef tea—about two ounces of whisky and six ounces of beef tea. Dry friction with the hand or with a dry cloth, especially to the extremities if they are covered with clammy perspiration, will do much to bring about reaction, and also will lessen radiation from the surface by preventing evaporation of the perspiration. Morphine in small doses, an eighth of a grain or less, is also useful as a heart stimulant and as an anodyne if, when the patient becomes conscious, there is marked pain. The morphine not only acts as a stimulant itself, but prevents depression which would result from severe suffering. So much for the immediate treatment of shock. Under ordinary circumstances, when the shock is marked and yet not so profound as to be alarming, within half an hour strychnine can be pushed to a fifth of a grain, atropine to a fiftieth, caffeine to five grains or more, and digitaline to a twenty-fifth of a grain, or, what is really better, tincture of digi-

talis to half a drachm, with the fiftieth of a grain of nitroglycerin.

If the crisis passes and yet the patient remains in a markedly depressed state, the question of treatment for the ensuing twenty-four or forty-eight hours comes up. The use of external heat should be continued until the temperature of the body becomes normal, and even longer should the patient complain of chilliness. But the sheet anchors of safety are strychnine, digitalis, and whisky. In a marked case it is my habit to give the following order: To give hypodermically sulphate of strychnine, a thirtieth of a grain, one hour; tincture of digitalis, fifteen drops, with the fiftieth of a grain of nitroglycerin, the next hour; three grains of citrate of caffeine the third hour; and an enema of whisky, two ounces, and beef tea, six ounces, the fourth hour. This order I have had carried out many times for twenty-four, forty-eight, and even seventy-two hours. In the worst of cases, for its temporary effect, cocaine has been employed in addition to the above, also small doses of morphine if much pain and especially if great restlessness were present. It is my experience that most patients will take a fifth of a grain of strychnine in twenty-four hours without manifesting symptoms of strychnism. I have not employed the heroic doses described by some writers, such as half a grain within two hours, but in a desperate case, watching it carefully, I should not hesitate to give repeated doses of a fifteenth of a grain every half hour for a short time until some symptoms of irritation of the spinal cord appeared. We certainly have no more reliable exciter of the nervous and muscular systems than strychnine, nor any drug which is more capable of maintaining its effect.

Digitalis is also a very reliable drug in the treatment of shock. It is capable of whipping up the heart to increased work, especially for a few days and until a sustained effect can be secured by alimentation. This is exactly what is required in the treatment of shock. Digitalis has, however, one effect which is undesirable. It causes a contraction of the arterioles, and thus increases arterial pressure, so that while it whips up the heart to do increased work, it also hinders the heart through the increase in arterial pressure; hence it is wise in the treatment of shock to combine digitalis with nitroglycerin, which overcomes this bad effect of digitalis. The combination is much more effective than either drug alone. Caffeine is a pure heart stimulant and can be administered freely without evil consequences. Alcohol used judiciously and in not too large quantities is one of our most important remedies. In shock following abdominal operations it is best administered by enema combined with beef tea, which is itself a stimulant. Later in the case champagne by the mouth is often of service, but it fills only a partial indication and is not to be compared in value with whisky when this can be ingested and retained.

The management of the diet in the treatment of shock is also important. Immediately after an operation, accompanied by much shock, the stomach, as a rule, is not retentive; hence it is wise for a time in no case to administer much aliment of any description by mouth. Some hot black coffee or hot beef tea is as much as should be given. When

the stomach becomes retentive, light, easily assimilable food should be employed, as beef tea, broth, milk (preferably peptonized), egg-nog, punch, etc. These foods should be administered in small quantities, frequently repeated. The question of alimentation in the treatment of shock following abdominal operations offers certain peculiar difficulties. Under ordinary circumstances, when shock is not a special feature, it is the rule to administer no food to the patient who has had a celiotomy for from thirty-six to forty-eight hours after the operation. Then broths or beef tea, from two drachms to an ounce, or two drachms of milk with one of limewater, are given every half hour, and if retained the quantities are increased and the intervals lengthened until about the fourth day after operation the patient is put upon liquid diet, the amount being regulated largely by the appetite. But in cases accompanied by marked shock, if the stomach proves retentive, it is wise to begin the administration of milk or beef tea at the earliest feasible time, the quantity being increased as rapidly as in the judgment of the surgeon the patient is able to digest and assimilate. In some critical cases lives will be saved by judicious alimentation which would be lost were the usual rules applicable in abdominal surgery followed.

It may be questioned whether the term shock should be applied to conditions which persist for one, two, three, or more days. It is customary to consider that shock is of temporary duration, and that it ends either in the prompt death or in the recovery of the patient. But there are cases in which it is difficult to assign a name for the condition of patients if it be not shock. I refer to those cases in which the patient exhibits marked shock after operation, and in which, although after a time the temperature of the body becomes normal and remains so, yet the patient's vitality remains at a very low ebb, the pulse continues rapid, small, and feeble, the cutaneous circulation is not restored, the surface of the body being cool and pale, and where no other symptoms are present except those of pronounced asthenia. This condition must be called shock. The condition persists until it is relieved by alimentation, as the nerve and heart stimulants—strychnine, digitalis, and even whisky—are not curative. I have had patients die in this condition as long as a week after operation without having manifested other symptoms than those of pure asthenia, and in which the post-mortem examination showed no cause of death. On the other hand, I have seen patients recover from this condition, improvement becoming manifested upon the third, fourth, or fifth day, when it had appeared that death was imminent from failure of the heart and respiratory centers. It is in such cases that judicious alimentation is of the highest importance.

In this class of cases the administration of oxygen gas by inhalation is at times of service. All the vital functions are at such a low ebb that any agent which is capable of improving the processes of metabolism is of value. My experience with the use of oxygen for this purpose is limited to one case, which was one of marked shock following an operation for double pus tubes in a woman reduced to the last extremity by hectic. She went to bed with a

pulse of 180, with cool and blue skin, and every other evidence of the profoundest shock. The pulse did not fall below 145 for three days, near the close of which period there was every indication of early death from pure asthenia. The plan of treatment already detailed was followed out in her case, and in addition oxygen gas was administered during one day. It seemed to be of great benefit; at all events, she passed out of the shadow of death and made a good recovery.

INTUBATION IN THE ADULT.*

By GEORGE M. LEFFERTS, M. D.

I HAVE chosen this subject for two reasons: First, because it possesses certain elements of novelty, and thus meets a difficulty that stands in the way of a choice of any topic suitable for presentation to an audience of experts. Intubation in the child has been almost exhaustively discussed during the past few years, has long since passed its period of probation, and has assumed a well-defined position as a remedial resource for the relief of dangerous conditions. Intubation in the adult, on the contrary, as a glance at contemporaneous literature will show, is a question that has as yet had but comparatively little attention bestowed upon it. It therefore offers a suitable and, I believe, a fruitful field for our cultivation.

Secondly, this same topic having been selected for a general discussion in the tenth section of the coming Eleventh International Congress, and I, together with Dr. Schmiegelow, chosen to introduce it, it has seemed to me desirable that it should first be brought before this American audience, in the home of modernized and utilized intubation, in order that I might avail myself of your experience and criticism, and thus be able to give an authoritative and even national weight to what I may have occasion to say in Rome.

Any discussion concerning the question of intubation in the adult presupposes the theory that the ultimate object of the introduction of a proper tube into the diseased larynx is, first, to overcome the most urgent acute symptoms of obstructed laryngeal respiration; secondly, to restore, as far as may be possible, the interior of the stenosed larynx to its normal caliber, and even configuration, by relieving the stenosing conditions; thirdly, to obviate the necessity of resorting to either a laryngotomy or a tracheotomy; and, finally, to facilitate the withdrawal of the tracheal cannula in certain cases where difficulties arise to prevent it.

Regarded from these standpoints, we may either deal alone with the question of the technique of the procedure, illustrating its practice by the detail of cases, or, as I have chosen to do, discuss its theory, in which event such discussion practically resolves itself into an enumeration of a variety of intralaryngeal conditions for the relief of which the use of the large-sized or adult intubation tube has, within the past two or three years, been employed, together

* Read before the American Laryngological Association at its fifteenth annual congress.

with such criticisms and deductions as our present knowledge warrants of the practical value of the operation in such cases.

The intralaryngeal conditions alluded to, unheard of—unthought of, perhaps—in connection with intubation in the early days of the art, are many, varied, and sometimes even curious. Their number is rapidly extending, as keen observers are attracted to the possibilities and advantages of laryngeal intubation as a substitute for older and more incomplete measures. Still, it must be conceded that the subject is in its infancy and that our experience is not yet such as to give ample and reliable statistics upon which to formulate definite propositions. An essay, then, like the present will, of necessity, consist largely of a compilation of the ascertained facts and deal to a certain extent with much that is problematical or at least not proved, and may serve alone to establish a new point of departure for future and further research. Illustrations of the practicability, at least, of the following propositions are in the majority of instances forthcoming, and their clinical details can be found in our literature; other corroborative cases have been treated at my clinic at the College of Physicians and Surgeons, New York. Where such clinical proof fails, I still offer the proposition in the hope that future research will justify my venture. I have, upon due consideration, thought it desirable to sacrifice these details for the sake of conciseness, and because each case demanding intubation, whatever be the cause, must be treated according to the indications that it individually presents; in other words, precedent will not guide us.

None of the many successes that are reported have been easily won. Patience, ingenuity, manual skill have all been demanded; many failures need to be recorded. The general outcome of our experience, however, is such as to encourage further earnest pursuit of what is clearly attainable.

In my enumeration I shall not pause to discuss the question of intubation in either acute or chronic syphilitic affections of the larynx. I have elsewhere* advanced clinical evidence of its effectiveness and recorded my belief as to its great practical value. Both this evidence and my views have been amply corroborated in the three years that have elapsed since they were presented, and the procedures long since removed from the bounds of a possibility to the domain of an actuality. Nor do I consider it necessary to call attention to the now universally conceded value of intubation in membranous laryngitis further than to recall to recollection that in the adult it has been practiced under the same conditions and with the same brilliant results as in the child—this in many recorded instances.

Professions have recently been advanced, on good authority, of a cure of abductor paralysis of the vocal cords by means of intubation. That relief to the inspiratory dyspnoea may thus be given there can be no question, but that a *cure*,

as I understand the word, the restoration of normal physiological abductive or respiratory movements to the vocal cords can thus be obtained, I must doubt; the organic causes alone producing the paralysis would prevent it, were other reasons wanting. This statement applies to chronic cases, or paralyzes of long standing; in others, where the inspiratory dyspnoea is dependent upon a paresis of the abductor muscles from commencing acute degenerative processes in them, especially if these are of myopathic origin, or due perhaps to some temporary peripheral lesion, transient pressure upon or slight injury to the recurrent laryngeals, the maintenance, by means of the intubation tubes, of even a small respiratory opening at the glottis may not only avert the immediate performance of tracheotomy, but also stimulate normal physiological movement, and thus preserve muscular nutrition by exciting a certain degree of muscular activity; the experiment is at least worth a trial. This latter indication also exists, and I believe has been successfully met, when the tubes were employed early in the case, in those instances where, after a tracheotomy, paresis of the abductors prevented the removal of the tracheal cannula.

Undoubtedly intubation is demanded and will have a certain value in relieving the dyspnoea dependent upon an acute bilateral abductor paralysis of constitutional origin. I have reported two such cases due to syphilis,* in which a cure of the paralysis followed an antisyphilitic treatment. In neither was the dyspnoea of such a grade as to necessitate a tracheotomy; had it been, or should it be in other like cases, intubation would relieve the temporary urgency of difficult respiration and obviate resort to a more formidable operation, aside from affording safety to the patient during the period of iodide administration and the establishment of its physiological and remedial effects.

Aside from these few—too few—instances, I must doubt the efficacy of intubation as a *cure* for bilateral abductor paralysis. There can be no difficulty in passing a tube between the closed but flexible vocal cords; there is no doubt as to the relief of inspiratory dyspnoea while it is in position, but the necessity of the patient's wearing it having arisen, can it again be dispensed with? It then, in chronic cases, becomes a choice between it and the tracheotomy cannula, and for permanent use the latter possesses advantages over the former. In one way alone in such cases can the intubation tube effect a passage, practicable and permanent, at the glottis which will allow of its eventual removal, or of that of a tracheotomy cannula—namely, by causing in the first instance pressure upon the parts most closely constricting it, then an ulcerative process and destruction of tissue, granulation and a molding of the inflammatory products about the tube, their organization and cicatrization following; such a process might eventuate in a cicatricial opening or canal between the now disorganized vocal cords that would remain sufficiently open for the passage of the respiratory current, especially if the process had been aided in the first instance by transverse incision of each vocal cord near its center.

* Intubation of the Larynx in Acute and Chronic Syphilitic Stenosis as a Substitute for Tracheotomy and the Method of Schroetter. A paper read before Section Twelve of the Tenth International Medical Congress in introducing a discussion upon Syphilis of the Upper Air-Passages. *Medical Record*, October 4, 1890.

* *New York Medical Journal*, December, 1878.

I can not, however, regard such a result, even if attainable, as a cure for abductor paralysis. It could only be reached by long, tedious, and difficult steps; the outcome would always be problematical, and tracheotomy at the outset or the retention of an already existing tracheotomy wound seems to me preferable.

Turning to another class of cases, where, it may be, a better promise of success is before us: intubation is doubtless indicated in some cases of laryngeal dyspnoea dependent upon abductive immobility of the vocal cords, due to *ankylosis* of the arytenoid articulations from either constitutional causes leading to laryngeal affections or non-suppurative adhesive arthritis due to local inflammatory changes, perhaps to mechanical fixation of the joints, by plastic infiltration of the tissues in their neighborhood, or by cicatrices of the same parts due to injury, typhoid, syphilis, or other ulcerative conditions, all of which bind them in an immobile position. In such instances well-directed pressure by means of a series of graded and even specially shaped intubation tubes will, it is believed, exert—indeed, in one or two reported instances at least has exerted—a favorable influence in promoting absorption of the effused material, or, by forcibly breaking up cicatricial attachments, has freed articular movement. This aside from the relief that the use of the tubes has afforded to respiration and the fact that tracheotomy may thus be avoided.

A novel but very reasonable indication for the use of an intubation tube is as an intralaryngeal splint in cases of fracture and displacement of the laryngeal cartilages due to direct injury. In such instances, after remolding the distorted parts of the cartilages into normal shape and position by external manipulation, the internal use of a large-sized tube will be of service in retaining them there during the process of repair. This retention may be aided by the employment of such external supports and dressings as are indicated under special circumstances.

The intubation in this same class of patients meets a second requirement that commonly arises—namely, acute dyspnoea due to oedematous infiltration or to the development of hæmatomata, usually of the aryteno-epiglottic folds, as has been shown in cases treated at my clinic. Two serious results of fracture of the larynx are thus possibly avoided—the necessity of immediate tracheotomy, and remote distortion or stenosis of the laryngeal cavity.

In chronic stenosis, the outcome of intralaryngeal conditions produced by fracture of cartilages that might perhaps have been averted by the timely and proper employment of the above measure, we have had at our clinic ample illustration of the excellent service rendered by intubation in dilating cicatricial contractions, and even in some measure replacing distorted parts. One such noteworthy result has recently been reported.

Another novel indication may perhaps in the future be successfully met by employing a proper sized and shaped intubation tube in cases of compression of the larynx or upper trachea from external causes, thus maintaining a respiratory passage. It has already been used for this purpose in acute tracheal stenosis caused by the pressure of an acute thyroiditis.

The tubercular larynx does not commend itself for many reasons as a proper site for the sojourn of an intubation tube. Still, the operation of intubation has been successfully performed more than once in laryngeal phthisis for the relief of dyspnoea dependent upon chronic oedema, for perichondritis, and for bilateral abductor paresis due to ankylosis of the arytenoid articulations—in these cases to the exclusion of tracheotomy. Perhaps in the future our experience may lead us to prefer it and to employ it exclusively. Either operation may only be chosen; in extreme cases either can give but temporary relief; to-day it seems to be simply the choice of the lesser of two evils.

In the treatment of the acute inflammatory affections of the adult larynx and their results intubation will play no unimportant rôle in the future if we may judge from the brilliant service that it has already rendered in the acute laryngeal diseases of childhood. Acute subglottic laryngitis is rare in the adult, but not unknown. Its symptoms are those of laryngismus stridulus in the child, and the diagnosis as to cause not difficult if the laryngoscope is used. To my knowledge, however, mistakes have been made, the rarity of croup in the adult and the default of a direct examination misleading the attendant into the performance of a tracheotomy in one case and to preparations for it in another. In any instance, in the adult, where the deep-red-colored mucous membrane can be seen to bulge out symmetrically in smooth, rounded masses from beneath the vocal cords, notably encroaching upon the subglottic space; where dyspnoea, sometimes spasmodic, always urgent, demands prompt assistance—intubation affords a reliable means of assured relief.

This is true also in those morbid conditions of the larynx characterized by an extensive and sudden serous infiltration of the loosely attached parts, in which the oedema is the prominent and practically the only local lesion. Ample experience has proved the efficacy of intubation and the fact that it alone may be depended upon when scarification fails to relieve the oedematous parts. The day of tracheotomy in oedema of the glottis has probably passed. In one instance at least, upon record, intubation has been practiced in erysipelas of the larynx; and the temporary use of the tube, to the exclusion of other and harsher measures, naturally suggests itself as a sensible and practical means of relieving the dyspnoea incident to traumatic laryngitis, especially that due to scalds and burns.

That acute perichondritis, especially of the cricoid and of whatever specific nature, may usually be combated, as far as its most urgent symptom—dyspnoea—is concerned, by the same measure, will, I think, be conceded.

Spasm of the glottis in the adult, usually purely reflex in character and rarely dependent upon any morbid lesion of the nerve centers, an affection involving discomfort and apprehension rather than danger, has in a number of instances upon record imperatively demanded the performance of tracheotomy. It seems to me more reasonable, in view of the temporary necessity for the use of any instrumental aid, to substitute the comparatively simple and safe intubation for the more serious procedure. The former operation has

been employed, but unsuccessfully, in a girl for pronounced aphonia spastica.

Among the many chronic affections of the larynx are found at least two conditions in which an intubation is of service in replacing older, more severe, and less perfect measures. First, in that rare form of chronic laryngitis in the adult that develops mainly in the subglottic region and results in certain hypertrophic changes that seriously encroach upon the breathing space. Energetic surgical procedures, usually at last a tracheotomy, have in the past been necessarily practiced to relieve life-destroying dyspnea. For the future, I believe that progressive intubation, dilatation with partial or even complete resorption of the hyperplastic tissue by means of regulated and directed pressure, will answer the indications and largely supplant all the other surgical operations that experience has so often proved to be ineffectual in opening and maintaining a respiratory passage.

Progressive intubation has been used, so the records show us, in cases of general hypertrophy of the laryngeal mucous membrane and resultant partial stenosis with some measure of success, and certainly played an important part in the result attained by Roaldes in his case of atresia of the larynx dependent upon adhesion of the vocal cords, and general distortion of the laryngeal cavity due to cicatrization following catarrhal ulceration.

It is hardly conceivable, in these days of precision in diagnosis and improved instrumental aids, that a multiple papilloma of the larynx in the adult would be allowed to attain such a size as to interfere seriously with respiration; still, it might happen; also that proper instruments were not at hand for the endolaryngeal removal of the neoplasm. In this emergency intubation would be preferable to tracheotomy as a temporary means of relief to the dyspnea and to afford time for other operative steps. Several such cases are recorded as occurring in children, and have been brought to a successful issue by such an expedient.

Two procedures, thus far only employed in the case of children, may have their value in certain rare instances in the adult. The first of these is an intubation with a series of progressively graded tubes, having for its ultimate object either the necrosis or interstitial absorption of the imperfectly organized tissue of the papillomatous growth by continued pressure. I can not believe that such a procedure will ever find general acceptance, being far inferior, both in intent and execution, to several other well-recognized and more effectual instrumental means of removal.

The second suggestion concerns the employment of large, thin-walled cylindrical intubation tubes as an aid in the removal of difficult laryngeal neoplasms. Each tube is provided with an appropriate fenestra that looks toward the exact site of the growth. The tube introduced, the growth should appear within the fenestra, and is then removed from the lumen of the tube by forceps, curette, etc., without chance of injury to surrounding parts. It appears upon the mere reading that such a procedure might be of service in affording protection in those cases of broad, sessile growths, firmly incorporated with the underlying tissues that are so difficult of radical extirpation, and

where, for instance, thorough and deep curettement is necessary.

Still more promising does it seem as an aid in the removal of neoplasms located in the subglottic region, one notoriously difficult of access. The separation and immobility of the vocal cords, secured by the introduction of the large fenestrated tube between them, the location of the exact site of the growth with the assistance of said fenestra, perhaps its direct presentation within it, should theoretically render what has always been a serious operation a more practicable and easier one. It should be added that it will require a practiced and skillful hand.

Cases occur in which small foreign bodies lodge in the larynx—small enough to pass the lumen of a special intubation tube of large caliber, yet large enough to cause by their presence laryngeal dyspnea, either immediately by reflex spasm or remotely from œdema and swelling, the dyspnea being urgent enough to indicate a tracheotomy, but in which, as experience has shown, intubation answers every purpose, as follows: Either the foreign body is dislodged upon the mouth of the tube during its introduction and is at once expelled through it, or it is pushed from the larynx into the trachea, and thence, being loose, is expelled through the tube by violent coughing.

In other cases where the foreign body is large enough to dangerously occlude the glottis, too large to pass through the intubation tube, suffocation imminent, and for any reason tracheotomy not immediately available, I believe that intubation is indicated to gain time and obviate a pressing necessity, when it is a possibility to insert the tube through the larynx and past the foreign body.

It has been suggested that intubation will be effectual in preventing the dangerous results of reflex laryngeal spasm when the foreign body in the air-passage is of a fluid character; blood, for instance, passing suddenly and in large quantity into the trachea in pulmonary hemorrhage, operations upon the mouth, throat, etc., provokes reflex spasm in its violent but ineffectual efforts to pass quickly in large volume through the larynx, and asphyxia ensues from its fatal accumulation in the trachea and bronchi. The temporary use of a large-sized tube would prevent the excitement of such laryngeal spasm by affording a free and unimpeded exit for the collection of fluid in the trachea.

My enumeration of suitable or probable good causes for an intubation must now include those so-called obstacles to the removal of a tracheotomy cannula that experience shows us not uncommonly occur when its withdrawal has been unduly delayed to a time long subsequent to the infliction of the tracheal wound. A study of the nature of these obstacles is sufficient to render at least reasonable the suggestion that we have in the intubation tube a means of overcoming many of them, and the theory has been verified in practice in some instances.

When dyspnea is dependent upon a stenosis caused by excessive granulation tissue springing from the upper borders of the laryngotomy or tracheotomy wound and filling the lower larynx or upper trachea, or when inflammatory swelling or hyperplastic hypertrophy of the laryngeal mu-

cous membrane below the glottis and above the limits of the wound into the air-passage exists, intubation surely will be of service; its good results have been already recorded in our literature.

Cases in which a cicatricial stenosis or a membranous web has developed, either at the site of the original incision, at some point above it, or in the trachea itself, as a result of undue pressure by the cannula, likewise present a suitable indication for the operation.

The question as to the value of intubation in overcoming the obstacle to the removal of the tracheotomy tube presented by the bilateral-abductor paresis that may be a sequel to the operation has been elsewhere mentioned in this paper.

Finally, I raise the query as to the possible service of an intubation in those curious, often unexplainable cases of inspiratory spasm that usually immediately, perhaps remotely, follow the attempted removal of the cannula.

In the three years that have elapsed since my paper on intubation in the adult larynx in syphilis was read at Berlin* no valuable modifications in the technique of the operation there described have been offered and no changes in the armamentarium suggested that are of any great importance. Both the theory and the practice of the art then remain practically the same, and I need occupy no time in repetition of what is already both known and conceded. My further experience has taught me that some boldness in the treatment of acute cases of laryngeal stenosis, a ripened judgment in the proper selection of chronic ones, the acquirement of considerable manual skill in the use of instruments, a competent knowledge, alone taught by practice, as to the use and change of suitable tubes, and, finally, both patience and persistence, are all needed to crown intubation with success. Just in proportion as these qualifications are forthcoming will the statistics of the operation improve in times to come. What I have written concerning the indications for the use of the intubation tubes in the adult is based solely upon the knowledge of to-day.

My summary is by no means conclusive; it will, I believe, be materially increased in the future as new indications present themselves; it will also need some modification, as certain indications are discarded as being impracticable of fulfillment. Meanwhile the need is for a larger collection of facts well observed by many persons. It has been shown that deductions drawn from the few at present at our disposal can not in many instances be regarded as conclusive. New facts, therefore, are desirable, and, widely discussed, tested, and, if possible, proved, must lead to advancement both in the science and in the art of adult intubation. To direct attention to this present need of increased observation, to record the known and encourage research for the unknown, has been the purpose of this essay.

* Intubation of the Larynx in Acute and Chronic Syphilitic Stenosis, p. 16 et seq. Reprint from the *Medical Record*, October 4, 1890.

THE RELATIONS OF THE HEART AND LUNGS TO THE ANTERIOR CHEST WALL,

AS DETERMINED BY COMPOSITE PHOTOGRAPHY.*

By IRVING S. HAYNES, Ph. B., M. D.,

DEMONSTRATOR OF ANATOMY IN
THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK;
MEMBER OF THE SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL,
OF THE NEW YORK COUNTY MEDICAL SOCIETY,
OF THE ASSOCIATION OF AMERICAN ANATOMISTS, ETC.

(Concluded from page 568.)

COMPARATIVE MEASUREMENTS.

1. BASE OF THE HEART:

- a. "Level of second costal cartilages" (Quain, Gray).
- b. "Below level of second costal cartilages" (McLachlan, Allen, Sibson).
- c. "Second right interspace to left first interspace" (Wilson).
- d. "Just below middle of right to above middle of left second interspaces" (Haynes, Subject I).
- e. "Upper border of the third costal cartilage" (Holden, Treves).
- f. "Junction of third cartilage with right border of sternum" (McClellan).

FIG. 1.—Subject I. Composite photograph of the chest and heart.

- g. "Upper margin of third right cartilage to center of second left space" (Haynes, Subject II).
- h. "From center of third right space to upper margin third left cartilage" (Haynes, Subject III, suspended vertically).

2. LENGTH OF BASE:

- a. Not given (Quain, Gray, McClellan).

* Abstract read before the Sections in Anatomy and General Surgery of the First Pan-American Medical Congress. In the first portion of this article, published in the *Journal* for November 11th, the following errors should be corrected: Page 565, second column, tenth line from the bottom, for "cross the median line at its seven-and-a-half-inch point. Over the xiphi-sternal articulation to the left," etc., read *cross the median line at its seven-and-a-half inch point over the xiphi-sternal articulation To the left, etc.*; page 567, first column, twenty-first line, for "at" read *opposite*.

b. "Half an inch to right and an inch to the left of sternum" (Holden).

c. "Half an inch to right and an inch and a half to left of sternum" (McLachlan).

FIG. 2.—Subject II. Composite photograph of the chest and heart.

d. "An inch to right and two inches and a half to left of sternum" (Wilson).

e. (Haynes) Subject I. An inch and a quarter to right and an inch and a half to left of median line, total two inches and three quarters. Subject II. An inch and five eighths and three quarters of an inch, respectively, total two inches and three eighths. Subject III. An inch and

FIG. 3.—Subject I. Composite photograph of the chest and lungs (anterior border).

an eighth and an inch and three eighths, respectively, total two inches and a half.

3. APEX POINT:

a. "In fifth left interspace three inches and a half from median line" (Quain, Gray, McLachlan, McClellan).

b. With reference to left nipple.

"An inch and a half below and three quarters of an inch to inside" (Quain, Gray).

"Two inches below and an inch to inside" (Holden).

"Two inches below and half an inch to inside" (Wilson).

c. "Fifth left interspace at costo-chondral articulation" (Treves).

d. (Haynes) Subject I. Fifth left space two inches and a quarter from mid sternal line (at its seven-inch point). Subject II. Behind center seventh left cartilage three quarters of an inch from mid-sternal line (at its seven-and-a-half-inch point). Heart in I distended, in II contracted. Subject III. Behind interchondral articulation between fifth and sixth cartilages, an inch and a half from mid-sternal line (at its seven-and-a-half-inch point). Subject suspended, heart moderately distended with blood.

4. RIGHT BORDER: The farthest point reached from the mid-sternal line. Quain says an inch and a half; none of

FIG. 4.—Subject II. Composite photograph of the chest and lungs (anterior border).

the other writers consulted mentioned it. (Haynes) Subject I. An inch and three quarters over fourth cartilage. Subject II. An inch and three quarters over fourth cartilage. Subject III. An inch over fourth cartilage.

5. LEFT BORDER: Farthest point reached from the mid-sternal line.

None of the above-named writers refer to it.

(Haynes) Subject I. Heart distended—"in diastole"—two inches and seven eighths over the center of the fourth interspace. Subject II. Heart contracted—"in systole"—seven eighths of an inch over center of fifth cartilage. Subject III. Midway between "systole and diastole," two inches over fourth interspace.

6. LOWER BORDER: The point at which it crosses the sternum—

a. "Bottom of the sternum" (Holden).

b. "Ziphi sternal articulation" (McLachlan).

c. "Upper third of ensiform" (Quain).

d. Haynes. Subject I. Middle of ensiform. Subject II. Zephi sternal articulation. Subject III. Middle of ensiform.

7. AREA OF CARDIAC DULLNESS IN INSPIRATION:

a. (Quain.) "Two lines from point of apex beat to the

middle line of the sternum—one horizontal, the other obliquely upward to between the fourth cartilages."

b. Gray quotes from Holden.

c. Holden quotes from Latham.

"Make a circle, two inches in diameter, round a point midway between the nipple and end of the sternum."

d. Treves quotes from Latham.

e. (McClellan.) "Line from middle of sternum, opposite fourth left costal cartilage, to the point of junction of the left fifth rib and its cartilage, and from this point horizontally back to sternum."

f. (Haynes.) Subject I. Heart expanded. A *quadrilateral space*, bounded on right by median line, below by lower border of heart, above by line from middle of fourth cartilages, along upper margin of fifth left cartilage, to an inch and a quarter from median line on the left, and from the last point draw a line downward to intersect the lower border of the heart three quarters of an inch from the left of the median line. Subject II. Heart contracted. All of the heart to the left of the median line and below the lower margin of the fourth left cartilage. Subject III. Lungs (in expiration) collapsed. Entire lower two thirds of heart to left of median line and below the upper margin of the fourth left cartilage.

8. AURICLES:

a. (Quain.) "The right auricle lies behind the sternal ends of the third, fourth, and fifth cartilages and the intervening portions of the intercostal spaces, and is also partially covered by the right edge of the sternum.

"The point of its auricular appendage is exactly behind the middle line, on a level with the upper border of the third costal cartilage.

"The left auricle extends vertically from the level of the lower border of the second left cartilage to the upper border of the fourth (sternal end).

"The apex of its appendage is in the lower part of the second intercostal space, or behind the third costal cartilage, about an inch and a quarter from the left of the sternum."

b. (Haynes.) Subject I. Right: The outline in the photograph is markedly "ear-shaped." It is behind the first inch of the third right costal cartilage, with the adjacent border of the sternum and the third space.

Left: Oval outline, half an inch by an inch, placed over a portion of the second space and third cartilage, the center of the area being an inch and a quarter from the left of the median line, and its long axis extending downward toward left.

Subject II. Right: Pear-shaped outline, base uppermost. Covers first inch from sternum of third right cartilage and space. Left: Behind the chondro-sternal articulation of the third left cartilage; oval-shaped; long axis as in No. I.

Subject III. Right: Distinctly auricular shaped. Includes fourth and fifth right cartilages for an inch from sternum and the included space, with the right half of sternum opposite the fourth chondro-sternal articulation. Left: Behind the third left cartilage, its center an inch and a quarter from the median line, its long axis inclined as in No. 1, and its shape the same.

9. AURICULO-VENTRICULAR GROOVE:

a. (Quain.) "The auriculo-ventricular sulcus corresponds with a line drawn obliquely upward from near the sternal end of the sixth costal cartilage on the right side to the third cartilage on the left.

b. (Haynes.) Subject I (approximately stated). A curved line with the convexity upward from the upper margin of the fourth right cartilage, an inch and three quarters from the median line, to the middle of the third left cartilage, an inch and three quarters to the left of middle line. This line crosses the center of the sternum on a level with the lower border of the third cartilages. Subject II. The line takes the same course as in I, except it ends at the lower margin of the third left cartilage, seven eighths of an inch from the median line. Subject III (suspended). A line convex upward from the upper margin of the sixth right costal cartilage, an inch from the median line, to the lower border of the third left cartilage, an inch and three eighths from the central line. The sternum is crossed on a level with the lower border of the fourth cartilages.

10. AORTA. First portion:

a. Commences "behind the sternum, on a level with the lower border of the third costal cartilage on the left side, and rises as high as the upper border of the second costal cartilage of the right side. Its length is about two or two and a quarter inches" (Quain).

b. "Commences on a level with the lower border of the third costal cartilage behind the center of the sternum, passes obliquely upward to right side as high as upper border of second right costal cartilage. It is about two inches long" (Gray).

c. "Its origin is on the left side of the middle of the sternum, about on a level with the lower border of the third costal cartilage, ascends with a slight curve, the convexity looking forward and to the right side as far as the upper border of the second costal cartilage of the right side. It is about two inches in length" (Holden).

d. "The aortic opening is behind the left border of the sternum, close to the lower edge of the third cartilage. The trunk ascends behind the second cartilage of the right side" (Treves).

e. (Haynes.) Subject I. Its axis corresponds to the median line. It is about an inch wide, and reaches from the upper border of the third cartilages to the middle of the cartilage of the first rib. It is about two inches long. Subject II. The aorta reaches from the upper border of the third right cartilage to the upper margin of the first cartilage. It is entirely to the right of the median line for the first two thirds of its course, and only curves toward the left after reaching the upper margin of the second cartilage. Same length as in Subject I. Subject III (suspended, not injected). Reaches from the upper level of the fourth cartilages at their sternal junction, entirely to the right of the median line, upward to the lower level of the first cartilage, where its center is behind the mid-sternal line.

11. PULMONARY ARTERY:

a. (Quain.) "The pulmonary orifice is placed opposite the upper margin of the third left costal cartilage, close to the sternum. The artery proceeds upward to its bifurcation

behind the second costal cartilage. It is nearly two inches long."

b. (Treves.) Essentially the same as Quain.

c. (Gray, Holden.) Do not give its surface relations.

d. (Haynes.) Subject I. Begins on a level with the lower border of the third cartilages, its center being half an inch to the left of the middle line. It proceeds upward and toward the left, and terminates just above the lower margin of the second left cartilage. Here its center is about three quarters of an inch to the left of the median line. The artery is a little over an inch wide and an inch and a half long. Subject II. Begins on a level with the lower margin of the third cartilages; its center behind the median line proceeds upward, inclining a little to the left, and ends on a level with the upper border of the second cartilages, its center being a quarter of an inch to left of middle line. It is about an inch wide and an inch and a half long. Subject III. Begins on a level with the lower margin of the third left cartilage, entirely to the left of the middle line, being about an inch and a quarter wide; passes upward to opposite the middle of the second left cartilage, where the center of the vessel is three quarters of an inch from the left of the median line. It is a little over an inch wide at its beginning and about an inch and a half long.

12. CORONARY ARTERIES. Subject I (heart distended): They run nearly vertical and parallel with the median line, the right an inch and the left an inch and three eighths from the same, the former from the lower border of the third right cartilage and the latter from the middle of the third left cartilage, and each extends to the lower level of the sixth cartilage. Subject II (heart contracted): The right artery is at an average distance of seven eighths of an inch from the mid-sternal line, parallel with the same (nearly), and extends from the upper border of the fourth to the upper border of the sixth cartilage. The left is parallel with the central line and three quarters of an inch from it, and reaches from the lower level of the third cartilage to the apex. Subject III (heart moderately distended): Right, from the upper border of the fifth cartilage close to the sternum to the middle of the ensiform. Left, from the lower margin of the third cartilage an inch to the left and parallel with the median line toward the apex.

13. THE ANTERIOR MARGIN OF THE LUNGS and the extent of their contact during inspiration:

a. (Quain.) "Meet at junction of manubrium and body of sternum, descend together, right sometimes projecting a little to left of middle line, as far as fourth costal cartilage; right lung continues straight course to sixth costo-chondral articulation; left slopes outward behind fifth costal cartilage, indicated by a line from fourth left chondro-sternal articulation to apex point."

b. (Gray, Holden.) "Anterior border of right lung corresponds to median line from junction first and second pieces of sternum as low as sixth costal cartilage. Anterior border left lung lies in middle line only as far as fourth costal cartilage."

c. (Treves.) "Meet in middle line at junction of manubrium and gladiolus; right continues vertically downward behind middle line to sixth chondro-sternal articulation;

left keeps close to right to fourth chondro-sternal articulation, when it turns off, following a line from fourth cartilage to apex of heart."

d. (Haynes.) Subject I: Converge from the apices and meet at the level of the upper border of the second cartilages a quarter of an inch to the left of the median line and run parallel with the same to the level of the upper border of the fourth cartilages. The right lung continues at the left of the middle line as far as the upper margin of the sixth chondro-sternal articulation, when it crosses to the right. The left turns outward along the upper margin of the fifth cartilage. Length of contact, nearly three inches. Subject II: The anterior border of the right lung crosses to the left of the middle line on a level with the upper border of the second cartilages and continues straight down to the lower level of the sixth costal cartilages at the sternum. The left nearly meets the right at the lower level of the second left costal cartilage, continues nearly in contact (and opposite the third space in actual contact) to the level of the upper border of the fifth left cartilage at the sternum, along the upper margin of which it passes to the left.

14. POINTS ON THE MID-STERNAL LINE opposite the centers of the sternal ends of the costal cartilages:

NUMBER OF CARTILAGES.	Subject I, male.	Subject II, male.	Subject III, female.
	Inches.	Inches.	Inches.
First	1 $\frac{1}{2}$	1 $\frac{1}{2}$	1
Second	2 $\frac{1}{2}$	2 $\frac{1}{2}$	2

15. RELATIVE POSITION OF THE NIPPLES: All the authorities agree in placing them in the fourth interspace three quarters of an inch external to the junction of the ribs and cartilages, or rather more than four inches from the median line.

In the two male subjects (I and II) the nipples were over the lower half of the fourth ribs, three inches and a half from the median line; in the female subject (III) they were four inches from the median line, the right in the center of the fourth interspace, and the left over the lower margin of the fourth rib. In the males the measurements were made upon the thorax after removal of the superficial tissues; in the female upon the exterior of the chest before such dissection.

From a comparison of the preceding quotations and the original measurements we see that at many critical points there is a wide difference between the accepted re-

lations given in the text-books and those revealed by composite photography.

As regards the lungs, these differences are so small as to be of little importance, but in reference to the heart they are so pronounced as to make us wonder if the currently stated relations of heart and chest do not need revision. For example, is it not possible—nay, more than probable—that the authorities in placing the apex beat three inches and a half to the left of the median line have gone at least an inch over the mark? For the apex point in Subject I, where the heart is fully distended, is only two inches and a quarter from the median line. And it can not be said in explanation of this difference that the heart has been moved bodily toward the right. It has not, we can see, for its right border only reaches an inch and three quarters from the median line.

And it can not be maintained that the heart has been foreshortened by the camera at the expense of the chest, for the heart in the photograph is nearly five inches wide. Besides, this error of foreshortening is prevented by *measuring the distances upon the bony framework of the chest itself* before taking the photographs, and any foreshortening of the heart is compensated for by the same occurrence in the image of the chest, and the results are unimpaired.

Moreover, the heart has not received complete treatment by the authorities quoted, in that its auricles, its borders, and its great vessels have not been traced in sufficient detail upon the bony framework of the chest. This is due, no doubt, to the uncertainties of the methods used for ascertaining these relations. In these composite photographs the relations lost by the former methods are brought out with remarkable clearness and can be readily traced, and their details have been given in the preceding pages, too full to produce attractive reading, but not, I hope, for accurate reference.

In concluding this paper I offer the following summary of the external relations of the viscera in question.

These results comprehend the conclusions derived from the statements of the authors consulted and from my own observations:

CONCLUSIONS.

1. Base of Heart: A line crossing the sternum obliquely from the upper margin of the third right to the lower border of the second left costal cartilage, an inch and a half from the median line on each side.

2. Apex: In the fifth space near the upper margin of the sixth costal cartilage, two inches and a half to the left of the median line.

3. Right Border: From the right end of the base curved slightly outward to reach a point an inch and three quarters from the right of the middle line over the fourth cartilage and ends at the center of the fifth cartilage an inch from the mid-sternal line.

4. Left Border: From the left end of the base with a convexity outward to the apex. It reaches its greatest distance (three inches) from the sternal center over the fourth space.

5. Lower Border: A line curved downward at its beginning (at the lower extremity of the right border) and

ending at the apex, and slightly convex upward in its center as it crosses the middle of the ensiform.

6. Heart Dullness: A *quadrilateral* area to the left of the median line and below the upper border of the fifth cartilage, nearly two inches in vertical and an inch and a half in extreme lateral measurements.

7. Auricles. Right: "Ear-shaped," facing to the left, covering the first inch of the third right space and cartilage with the portion of the sternum adjacent to the latter. Its long axis measures about two inches and is inclined from above downward and outward. Left: Is a small oval space half an inch by an inch, its center an inch and a quarter to the left of the median line behind the second left space and third cartilage. Its long axis is directed from above downward and outward.

8. Auriculo-ventricular Groove: Is indicated by a line from the right to the left heart border, beginning on a level with the upper margin of the fourth right and ending on a level with the lower edge of the third left cartilage. This line is convex upward and crosses the middle of the sternum on a level with the lower border of the third cartilages.

9. Aorta: A little more than an inch wide and about two inches long. Extends from the upper border of the third to behind the middle of the first cartilages. At its beginning and ending its center is behind the median line, but in the middle of its course the artery is convex toward the right.

10. Pulmonary Artery: About an inch and a quarter wide and an inch and a half long (in photograph). Begins on a level with the lower border of the third and ends behind the middle of the second left cartilages. Below its center is half an inch and above three quarters of an inch to the left of the median line.

11. Coronary Arteries: Both are nearly vertical; they incline slightly toward the median line at their lower ends. Right, an inch from the mid-sternal line. Extends from the upper border of the fourth to the lower border of the sixth cartilage. Left, an inch and three eighths from the middle line in expansion and three quarters of an inch in contraction of the heart, extends from the middle of the third to the lower border of the sixth cartilage.

12. The Anterior Margins of the Lungs in Inspiration: Right lies to the left of the median line, a quarter of an inch from and parallel with it from the upper margin of the second to that of the sixth cartilage (sternal ends). The left is in contact with the right from the upper border of the second to the mid-point between the fourth cartilages, where it turns downward and outward along the upper margin of the fifth left cartilage. Length of contact, two inches and a half.

a. MALE (average of two).	Inches.	Distance from each other.	Inches.	b. FEMALE.	Distance from each other.
First cartilage.....	1½	..	1
Second cartilage.....	2½	½	2	1	1
Third cartilage.....	3½	1½	3½	1½	1½
Fourth cartilage.....	4½	1½	4½	1	1
Fifth cartilage.....	5½	½	5	½	½
Sixth cartilage.....	6½	½	5½	½	½
Seventh cartilage.....	6½	1	6½	½	½

13. The centers of the sternal ends of the costal cartilages are opposite the distances on the mid-sternal line, measured from the suprasternal notch, as shown in the above table.

14. Nipples: Over the lower margin of the fourth rib, four inches from the middle line.

RECENT STUDIES

IN NAUPATHIA, OR SEASICKNESS.

SYMPTOMATOLOGY, DIAGNOSIS, PATHOGENESIS,
AND TREATMENT BY A NEW AND EFFICACIOUS METHOD.

By WINSLOW WARNER SKINNER, M. D. (PAR.),
FORMERLY SHIP'S SURGEON ON SEVERAL TRANSATLANTIC LINES, ETC.

SEASICKNESS is an affection about which there are many theories and for which a legion of different remedies have been vaunted. This is because it has not been thoroughly studied, and consequently no logical method of treatment has been settled upon that will oppose promptly, constantly, and efficaciously the numerous symptoms of this affection.

The object of this review of seasickness is to give the most complete description of the subject extant and to offer to the medical profession a means of combating the affection that can be relied upon.

There is hardly a morbid state to which man is subject that has resisted the prescriptions directed against it as much as this; there is hardly one which has caused the physician so many deceptions and the patient so much discouragement as this. Therefore the physician has in fact almost wholly renounced treating seasickness in the hope of positively curing it, and the patient rarely calls upon the ship's doctor to treat it. It is truly a strange spectacle of our times to see on board of a great transatlantic liner, for instance, hundreds of passengers violently seasick, keeping their berths, vomiting each instant, moaning, and really suffering atrociously, while the ship's physician, although possessing the medical knowledge and the therapeutic means of our day, is powerless to relieve them.

But this state of impotence in face of such an evil ought not to last indefinitely. Recent investigations made by the writer indicate that there is an efficacious treatment for naupathia, and that the physician will no longer be without arms against this affection. These arms, however,

are chosen from among substances at once the oldest and the most active in pharmacology.

It is not lightly and without reflection that the account of our investigations has been prepared for publication. We come with facts and figures and know whereof we speak. We lay them bare for the examination of all, that all may judge of the value of the method of treatment herein explained. Seven years have already passed since the first successful trials of this method of curing seasickness were made. During this time the substances recommended for administration have been thoroughly tried. Laboratory experiments* upon the lower animals were made by us in Paris with Professor Hayem's apparatus with the view of determining the effect of these substances upon the blood pressure. Above all, they have been tried upon the human subject a great number of times. The author has made a special study of seasickness, and his voyages as ship's surgeon amount to nearly sixty thousand miles, while more than twenty-five hundred passengers have been directly under his care. Written clinical reports, eighty-seven in number, of typical cases of naupathia form the basis of this article, and the number of times the remedies have been exhibited rises to over three hundred. He may therefore justly claim experience in the matter in hand. This experience was gained in voyages on French steamers plying between France and South America, between Belgium and the United States, between France and the United States, and between Portugal and the United States.

It was during a voyage from Havre to Buenos Ayres and return, on board the steamship Dom Pedro, that this method was employed for the first time. The long voyage lasted two months and a half and furnished ample opportunity to observe seasickness, and indeed not only among passengers but also among seamen. Details of many cases will be given in another part of this article.

I. SYMPTOMATOLOGY.—In order to accurately understand the pathogenesis of naupathia, which will be elucidated later on, it is necessary to have in mind the *principal symptoms* of this affection, which are much more numerous than former writers have supposed. It will subsequently be seen how these many and diverse symptoms are all united by a common underlying tie which, once perceived, not only explains and harmonizes these various phenomena, but also furnishes an explicit guide to their correction and the cure of seasickness.

1. The most important of these symptoms, which are also the most distressing to the patient, arise from the *central nervous system*, and especially from the brain (cerebrum) and the medulla oblongata. To this category belong the extreme prostration of the patient; the asthenia and feeling of great weakness, which render the seasick incapable of making the least exertion and which oblige them to keep abed days and even weeks; the vertigo, the terrible feeling of instability, as if all were about to disappear in an immense abyss; the cephalalgia, mostly frontal,

* W. Skinner, *Bulletin général de thérapeutique*, Paris, July 15, 1886, p. 29.

often temporal, sometimes general; the sensation of heaviness in the head, of constriction of the temples; the feeling of malaise, of indefinable torture; and, lastly the insomnia, which may and often does deprive the patient of all repose during several consecutive days.

The various reflexes (corneal, pupillary, pharyngeal, abdominal, tendinous, and plantar) have often been tested and found normal.

There is still an important symptom which had considerable influence in determining the treatment of seasickness by the new method; this symptom is *myosis*, which is often present in this affection. It is undoubtedly dependent upon the state of the nervous system, and indeed of that of the great sympathetic division of the nervous system. The interpretation of this phenomenon will be found in the third part of this article.

The pupils retain their reflex activity both by the action of light and by the effort of accommodation.

2. The digestive apparatus also presents a great contingent of symptoms, and these are the most striking to non-medical observers.* Mentioned in the order of the anatomical regions in which they occur, there is, first, coldness and pallor of the lips, ptalism, and the foul taste sometimes perceived in the mouth. The tongue, in uncomplicated seasickness, is always uncoated, rosy or pale, humid, and generally in a normal state.

Anorexia is one of the earliest symptoms that announce the approach of seasickness. Nausea follows closely; then appears the vomiting, which at first sight seems to be the principal and the most characteristic symptom of this affection. This last may be absent in light cases, but it is very rarely lacking in cases of average or of great intensity. At first alimentary, the vomiting next becomes mucous, then bilious. Hæmatemesis is not present in simple cases.

The act of vomiting is not without utility. It is not, however, in purging the body of certain matter supposedly noxious that its usefulness lies, but, in fact, by the *effort* which precedes and accompanies it, and which has for one of its effects the forcing of a certain quantity of blood to the brain and to the medulla, which stand in such need of it. In other terms, this effort momentarily activates the encephalic circulation, and the period of calm and of relative euphoria which follows may be due solely to this reflex act. Emesis may thus be regarded as an attempt on the part of Nature to re-establish the normal state of the organism.

From another point of view emesis is a cause of exhaustion of the patient's strength, not only by the violent muscular contractions, often repeated, which are necessary for its accomplishment, but also by the loss, often considerable, of nutritive albuminoid or mineral substances which are rejected by the mouth.

There is sometimes pain in the epigastric region produced by the numerous efforts at vomiting, and in some

cases the patients exhibit a veritable gastralgia due largely to abstinence from alimentation, but otherwise this phenomenon does not enter into the symptomatology of seasickness.

What is more important than the preceding, and more constant, is constipation, which, it is believed, never is lacking in uncomplicated cases. This may be more or less pronounced, but it constantly exists in simple cases. Its cause resides certainly in a paresis of the muscular tunic of the intestine. This point will be treated of again when the rôle of the ganglionic nervous system in the production of naupathia is dwelt upon in another part of this treatise.

The liver and the spleen present nothing abnormal; in any case, the latter does not acquire a volume sufficient to render it perceptible by palpation. The abdomen remains normal in its form, its consistence, and its sonority.

3. The physician obtains from the *circulatory apparatus* quite a series of signs and important symptoms, which furnish valuable indications for therapeutic measures. They indicate, in general, a *slowing of the circulation and a lowering of the arterial blood pressure*. The cardiac pulsations are weaker than the normal. As to their number, it follows from my observations that in men there is almost always diminution or bradycardia—several times the number was 57, 51, 48, and even 45 per minute (Case VIII); that in women the number is increased (tachycardia) as often as diminished, and not infrequently the number remains normal (maximum observed, 114 per minute, *without fever*; minimum, 51); and that in children it is almost always, if not always, increased (maximum 120, without fever).

The pulse constantly presents a *diminished resistance*, a greater depressibility than the normal. This is manifest in each patient in comparing his pulse during the attack of seasickness with that which he has when he is cured. The pulse is small, feeble, easily compressed, often perceptible with difficulty. It is regular and equal, without change of rhythm.

The capillary circulation appears retarded. The extremities of the patient, also the ears, the nose, the lips, are cold and clammy. The cutaneous circulation is so diminished that the skin presents several phenomena useful in establishing the diagnosis, and which will be examined in a moment.

In regard to the constitution of the blood in seasickness, there has been no opportunity to examine it.

4. The striated muscles subject to volition offer nothing in particular; the heart has already been mentioned.

The *unstriated muscles*, on the contrary, are evidently parietic, as was said in speaking of constipation. To such a state of paresis may be attributed the inertia of the intestine, that of the radiating fibers of the iris in myosis, and there may also exist a paresis of the muscular tunic of the blood-vessels, which would explain, in a certain measure, the lowering of the blood pressure.

5. The *skin* is extremely pale, cold, and often moist. Immediately before emesis occurs, synchronous with the nausea which precedes it, the skin receives a renewed wave of perspiration, which renders it still cooler and moister.

* Many of these symptoms might with reason be referred to the nervous system, but they will be named here as if they depended principally upon the organs with which they seem to be the more closely connected.

The natural color of the skin may disappear to such an extent that the patient has almost the aspect of a cadaver—an aspect sometimes increased by a slight greenish-yellow tint in very severe cases. This peculiar condition of the skin, the incessant vomiting, and the great prostration manifested by the patient would easily make a person unaccustomed to the sight believe that the sufferer before him was in danger of dying, so violent and so threatening are the divers symptoms. This state of the skin (pallor, abnormal tint, coldness, moisture) depends on the defective circulation in this organ, causing cutaneous anæmia.

6. The *urine* is remarkably diminished in quantity (oliguria). Hardly does the patient feel the need of evacuating his bladder once during the twenty-four hours, and even when he does so, it is only a hundred, two hundred, or possibly three hundred cubic centimetres that he passes, instead of the normal fifteen hundred. The quantity is so small that it is with difficulty that the physician can procure enough for analysis. Nevertheless, we have been able to get enough from several patients to make analyses thereof. In their cases the urine was clear, acid, amber-colored; devoid of sediment, free from albuminoids (albumin, peptone, or others) and from glucose. More research in this direction, however, is greatly to be desired.

7. Naupathia is an apyretic affection. The central temperature of the patient in simple cases does not rise above the normal, and it varies only within narrow limits. The maximum I have observed was 37.7°C .; rectal temperature (the minimum), 37.3° .

The general aspect of a person suffering from seasickness rather severely is well fitted to inspire pity in one observing him. The extreme decoloration of the countenance; the indifference of the patient to all that transpires about him, which is sometimes so great, it is said, that women lose the feeling of shame and modesty, and parents the parental love for their children; the sufferer's apathy; the distress depicted in his face and his attitudes; the moaning that escapes him; the lack of sleep and of all restorative repose; the constant nausea and emesis—all these phenomena witness to the existence of a really insupportable state of body and mind, which claims with a loud voice the relief obtainable from men of our profession.

II. DIAGNOSIS.—The diagnosis of this affection is so easy, in general, that any one, no matter who, is able to make it. There is no difficulty, except in certain cases which will be indicated below, or in those in which naupathia is complicated by the synchronous presence of another disease.* In certain affections of the digestive tract, for instance, vomiting occurs as a symptom, and it is not always easy to determine whether it is due to the local disease (gastritis, indigestion, helminthiasis, etc.), or to a general affection (seasickness). But if, with symptoms of a disease of the digestive tract, there is abnormal salivation, notable diminution of the frequency and abundance of urination, unusual paleness, coolness, and moistness of the skin, atresia of the pupils with conservation of their reflexes from

the action of light and of accommodation, absence of fever and presence of vertigo and of peculiar distress and prostration, then it is certain that the case is one of seasickness.

Shall we go farther and make a differential diagnosis between naupathia and another disease more frequent in children and in adolescents—quite rare among passengers on the sea, it is true, but which might, nevertheless, be observed there? This disease, extremely grave, presents several symptoms in common with naupathia. It is a disease characterized by an onset often rapid, especially in warm climates, by intense cephalalgia, by extreme prostration, by repeated emesis, and which is none other than cerebral meningitis. These symptoms, with pallor of the skin, which is sometimes observable in meningitis, are present in both affections, and when the latter is caused by insolation (which happens in the tropics), occurring during the first hours of a voyage, for instance, it is extremely important to be able to make the diagnosis with promptness and precision.

The signs which help to distinguish meningitis from seasickness of extreme or even medium intensity are relative to the cephalalgia, to the pupils, to the salivary secretion, to the vomiting, to the vertigo, to the peculiar distress and torture of the seasick, and to the temperature.

The cephalalgia of generalized cerebral meningitis is diffuse, and felt in all the regions of the encephalon at the same time, while in naupathia it is oftener limited to one of the anterior regions of the head (frontal, supra-orbital, or temporal regions). It is severer in meningitis, and the complaint it provokes from the patient is very different from that arising from the headache of the seasick.

The pupils are often in mydriasis in meningitis; they present a diminution or an abolition of their reflex contractility, and they are often unequally dilated. In seasickness, however, they are predominantly atresic and their reflexes are intact. Moreover, there is no photophobia in the latter.

The salivary secretion is little influenced in the former case; on the contrary, it is habitually increased in naupathia.

Emesis is less frequent, less noisy, less violent, and less frequently preceded by nausea in meningitis than in the other affection.

The temperature of the body is abnormally elevated in the first; it remains normal or else falls a few tenths of a degree in the second.

Finally, one might add that the pallor of the face in meningitis often yields place suddenly to flushing, and that without appreciable cause, while in naupathia scarcely does the paleness, even after vomiting, merge into a trace of color for a few moments.

Upon seas bordering on unhealthful countries where certain diseases reign endemically or epidemically, it is possible that cholera might be mistaken at first for seasickness. The pallor and moisture of the skin, the vomiting, the prostration, the anxiety of the patient, and the suddenness of the onset certainly render the two affections comparable to a certain extent in regard to their symptomatology. But in naupathia the diarrhoea, so frequent if not

* It is understood, of course, that the patient whose case is to be diagnosed is in a situation favorable to the development of naupathia—i. e., upon a boat, in a railway train, a carriage, or the like.

constant in cholera, is absent, as well as the thirst, the injection of the conjunctiva, the cadaveric aspect of the face, or else its typhoid appearance, and the notable hypothermia, also the hyperthermia, both of which may occur in cholera and are easily determined. It is unnecessary to longer insist on the elements of diagnosis of these two affections.

Certain *poisons* produce a symptom-complexus that can be confounded with seasickness. It is those forms of poisoning which include among their symptoms vomiting, prostration, pallor of the face, and distressing pain or anxiety that resemble the latter affection. But in cases of poisoning producing vomiting there is habitually diarrhoea also, which latter is foreign to naupathia. Again, the study of the temperature, of the seat and character of the pain, of the ejecta, and of the concomitant circumstances, will furnish a sufficient number of elements for the diagnosis of these two classes of affections.

Finally, in all *fevers* with sudden onset and having emesis among their prominent symptoms, the simple use of the thermometer will afford all necessary information for differential diagnosis.

III. The Prognosis of naupathia uncomplicated by other morbid states ought, in our opinion, to be always favorable as to the life of the patient. Some authors have maintained the contrary, but we have not found in the literature of the subject the relation of a single simple case having terminated in death. It is true that a person may have seasickness so severely and so long that his nutrition may suffer to a very great extent, as indeed one of my cases (XIII) shows. De Rochas* relates that a nun who sailed for Australia did not arrive there till the end of six months, and she was seasick during the whole time. She could retain nothing upon her stomach, and her emaciation was so great that on the day of debarkation she was reduced almost to a skeleton.

Similar cases have been observed when voyages were made exclusively by means of sailing vessels and which have consequently lasted a long time. But the sea has not been (to our knowledge at least) the cause of grave or fatal accidents in persons otherwise healthy. Such accidents as the production of a hernia, a cerebral hæmorrhage, or the rupture of an aneurysm, which might be occasioned by the effort of vomiting, should be laid to the account of an anterior abnormal or pathological state. As to miscarriage or premature parturition, we know of no authentic case in which it was caused by seasickness. Even in pregnant women almost at term, delivery seems not to occur before the end of the normal duration of gestation.

(To be continued.)

The Prize of the Alumni Association of the College of Physicians and Surgeons.—Our readers' attention is called to an advertisement of this prize which will be found in this issue of the *Journal*. The prize is open to all alumni of the college. It is to be hoped that it will not fail to be awarded because of the fact that no essay deemed worthy of it is submitted.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 9, 1893.

THE ANNUAL REPORT OF THE SURGEON GENERAL OF
THE ARMY.

The promptitude with which the surgeon general of the army prepares his annual report seems to be equalled by that of its printing and distribution, for within a few months after the termination of the fiscal year the public is in possession of the achievements of that year. The total expenses were \$104,538.80, although an additional expenditure of some \$65,000 will be made for supplies ordered previous to July 1, 1893, thus making a total of about \$170,000. This sum does not include the salaries of the medical officers or the money expended for the services of contract surgeons.

Over a thousand specimens were added to the museum, and more than eight thousand books and pamphlets were placed in the library.

Of forty-three candidates examined for admission into the medical corps, twenty were rejected for professional incapacity, seven were rejected for physical disability, four withdrew after partial examination, and twelve were found qualified. These figures are of considerable interest because they indicate either that a better class of men are taking the government examination or that the medical colleges are giving more thorough instruction, for the percentage of candidates that pass is higher than in former years.

General Sternberg says of the Army Medical School: "Although there is no need to teach medicine or surgery to well-educated graduates of our medical colleges, there are certain duties pertaining to the position of an army medical officer for which the college course of these young men has not prepared them; and certain of these duties are more important than the clinical treatment of individual cases of disease and injury, because the efficiency of a command, of an army even, may depend upon their proper performance. . . . The army medical officer is the health officer of his command; but the young graduate seldom is equipped with the knowledge or experience necessary to efficient action in this position. The course at the Army Medical School will prepare him to cope with the questions of practical sanitation that will be presented to him at every turn in his military career."

There is an account of the present status of the hospital corps and of its requirements that will be of interest to the many medical officers of the national guard.

The admission rate to the sick list was 1,270:42 in a thousand of strength, and is, excepting that for 1887, the lowest recorded admission rate. The per-mille of the non-effective was 39.6, a lower rate than that of the army of Italy, Great Britain, or Austria-Hungary.

The surgeon general recommends the introduction of electric lights into the Army and Navy General Hospital at Hot Springs; the use of white duck as the most suitable apparel for men of the hospital corps while occupied in ward duty; the reference of all plans for the construction or alteration of buildings or for sanitary improvements at military posts to a board of officers in which the medical department shall be represented; the disuse of casemates as living and sleeping rooms; the provision of quarters for a limited number of married enlisted men; the prohibition of the practice of flushing barrack floors so as to wash them; the construction of garbage crematories at permanent posts; and the establishment of post laundries.

There are the usual statistics regarding the military departments and the separate posts and the tabulation of diseases and injuries treated, and the volume is worthy of the high reputation of our army medical corps.

THE TREATMENT OF INGROWING TOE-NAIL.

In the November number of the *Revue de chirurgie* there is an article on ingrowing toe-nail by M. E. Nicaise. In regard to the treatment of this condition, the author says that it has been complicated by the number of procedures that have been devised. While he does not set out to enumerate them completely, he classifies them in a way to render their study easier. There are four methods of treatment. The first is simply a matter of dressing. The second comprises operations practiced on the nail alone. The third embraces operations on the soft parts. The fourth consists of operations involving both the nail and the soft parts.

As regards the dressings that have been proposed, they are innumerable. They have for their object to restrict the contact of the edge of the nail with the groove in the flesh surrounding it, and to treat ulceration in a desiccative manner; bits of charpie dipped in some astringent or slightly caustic substance, which may be varied *ad infinitum*, such as alum, tannin, tincture of iodine, iron perchloride, and silver nitrate, which are slipped under the nail. It may be assumed that the raw surface caused by the ingrowing of the nail is invaded by microbes, which, finding there anatomical elements that have ceased to be normal, fall to fulfilling one of the functions attributed to them by Nature—that of reducing the tissues into simpler elements. Antiseptic topical applications arrest the invading action of the microbes and heal the wound. At the same time that these topical applications are made to the ulcerated surface, it is sometimes an object to reduce the lateral swelling and replace the nail. Guy de Chauliac advised the use of a sheet of lead, which would at the same time raise the edge of the nail and compress the flesh; he also employed caustics, and, in order to allow of walking, covered the toe with a sort of cap of copper or silver, perforated "in order to allow the toe to breathe," he said. Bonnet used a dressing of prepared sponge, which pressed upon the pulp and caused it to retreat gradually from the nail; but this dressing was diffi-

cult to keep in place, and it required that the patient should be at rest. Finally, various sorts of hooks and plates have been devised for raising the nail, but everything of this kind is inadequate in the adolescent—for a relapse is to be apprehended. When the second toe has deviated above or beneath the great toe, the first indication is to restore it to its natural position.

The operations practiced on the nail alone are for the purpose of diminishing its transverse dimensions. With the idea that ingrowing toe-nail was due to too great a breadth of the nail, ablation of its median portion has been practiced, with approximation of the two remaining lateral portions, or ablation simply of the ingrowing portion and of half the nail, or finally of the whole nail. Not one of these procedures is founded upon a knowledge of the anatomy and physiology of the nail, consequently they do not answer the purpose. The same may be said of operations upon the soft parts having for their purpose the destruction of the overlying flesh; they are palliative operations and do not do away with the possibility of relapse, for the matrix is not destroyed. Nevertheless, there is a very ingenious procedure which involves only the soft parts and may be efficacious when the primary spatula form exists, namely, M. Guyon's: A parallelopipedon having the same length as the ungual border is cut out from the pulp; when the lips of the wound are brought together the prominence becomes smaller and recedes from the border of the nail. Sometimes a relapse follows this procedure.

In the fourth class of procedures a radical cure is aimed at; in order to obtain it, caustics, such as the red-hot iron, caustic potash, etc., are employed, but the best way is to resort to the knife. Baudens inserted the bistoury at the origin of the groove for the ingrowing nail and brought it out in front in such a way as to remove at one cut the matrix, the overlying soft tissue, and the incarnate part of the nail. By this method one is not sure of removing the matrix, so it is better to resort to the following means: In Follin's operation a transverse incision is made behind the nail, a longitudinal incision in the swollen soft tissue, and an incision parallel to the latter through the nail itself, in such a way as to remove the parallelopipedon comprising the matrix, the redundant soft tissue, and the incarnate edge of the nail; then the subungual derma corresponding to the portion of nail removed is excised. Gosselin employed a procedure analogous to Follin's, except that he removed the entire nail, a practice that is unnecessary and one that prolongs the treatment. In Théophile Anger's procedure a flap of the redundant soft tissue is made by transfixion, the bistoury being inserted posteriorly and brought out anteriorly, by which at one cut the same object is effected as in Baudens's procedure.

After having employed several methods, the author has definitively adopted the following, which is substantially Follin's: Local anesthesia is necessary, and that is effected by different measures, such as the application of a mixture of ice and salt; at present tubes filled with ethyl chloride are made use of, and their employment is very convenient. The foot is washed,

lathered with soap, and bathed with a strong solution of carbolic acid, the space between the toes, the toes themselves, and the nails being particularly cleansed; the toe is forced outward by its root between two fingers, and then an India-rubber tube is wound around the root. With narrow-pointed scissors about a quarter of the nail on the incarnate border is separated; with a strong forceps the portion of the nail thus separated is pulled out; then with the bistoury a transverse incision is made behind the matrix about five millimetres from the nail. This incision corresponds to the portion of the nail that has been removed, and it includes the whole thickness of the derma. The matrix is then removed to a point in front of the lunula, and then the ulcerated base of the groove from the border of the nail. It is necessary to take great care in removing the fungosities of the groove, in order to prevent subsequent suppuration. As for the unguinal derma situated in front of the lunula, it is sufficient to abrade it. There is thus formed an elongated raw surface, and the elevated soft tissue at the side presents a refreshed surface; this tissue is supple enough to be compressed into the place which was occupied by the portion of the nail that has been removed. Then the rubber tube that encircled the root of the toe is taken off, and a sponge wet with a strong solution of carbolic acid is held upon the wound for a few minutes; after that a strip of iodoform gauze about a third of an inch wide is so applied as to hold the projecting soft tissue down upon the wound by gentle compression; the toe is then enveloped in iodoform gauze and the other toes are separated from each other by absorbent cotton, which also covers the whole foot. Finally the dressing is held in place by a tarlatan band reaching as high as the instep. This dressing should be changed on the fourth or fifth day and once or twice after that, the patient being kept recumbent.

MINOR PARAGRAPHS.

ARSENIC AS A CAUSE OF MULTIPLE NEURITIS.

THE *Lancet* for November 18th contains a report of a post-graduate lecture on Some Symptoms and Varieties of Multiple Neuritis by Dr. Thomas Buzzard, physician to the National Hospital for Paralytics and Epileptics, London. The lecturer reminded his hearers that alcohol, diphtheria, septicæmia, gout, rheumatism, and diabetes were perhaps the most frequent causes of multiple neuritis, but among the exceptional causes was the administration of arsenic. A short time before he had seen a patient, the subject of congenital chorea, who had been treated with increasing doses of arsenic for two months. The largest dose, the man said, had been seventeen minims of Fowler's solution three times a day. While he was under the influence of this treatment his hands and feet became somewhat inflamed, and the soles of his feet, and especially the toes, grew red and tender. He complained of a "prickling, pins-and-needle" sensation. The cutaneous sensibility was impaired and the skin of the hands peeled. "The knee-jerk was abolished on each side. His feet felt like clogs, so that he could walk but little. Six or eight months afterward the knee-jerks were present, but "required re-enforcement." The cutaneous sensibility was still impaired in the hands. His fingers were clumsy and touches upon them gave rise to prickling feelings. He

was, however, gradually recovering. Alcohol and syphilis could be excluded as causes of this polyneuritis, which had developed while the patient was taking increasing doses of arsenic and which had gradually subsided when the administration of that drug was discontinued. Such a case represented, as it were, the artificial production of multiple neuritis, and might be usefully remembered, not only because it epitomized the symptoms of multiple neuritis, but might serve as a warning against a certain danger belonging to the employment of arsenic which was sometimes not considered.

PEANUTS AS AN ARTICLE OF FOOD.

In the *Berliner klinische Wochenschrift* (cited in the *Centralblatt für klinische Medizin*) Dr. P. Fürbringer treats of the peanut as an article of food rich in albumin, of which it contains forty-seven per cent., together with nineteen per cent. of fat and non-nitrogenous extractive matters. He recommends the use of roasted peanuts in the form of soup or mush. On account of their cheapness, peanuts are recommended as a popular article of food, especially in poorhouses and the like; moreover, they are recommended as an article of food for the corpulent, for diabetics, and for the subjects of kidney disease, in the last-mentioned of whom foods rich in animal albumin are to be avoided.

SOME USES OF SODIUM SALICYLATE.

In an article on this subject published in a recent number of the *Union médicale*, Dr. West is credited with recommending the use of the following formula in the treatment of amygdalitis: Sodium bicarbonate, one and a quarter drachms; glycerin, one ounce; peppermint water, three ounces. Of this a tablespoonful is to be taken every three or four hours. In the same article the following formula is mentioned as having been advised in stubborn cases of cold in the head: Sodium salicylate and syrup of orange peel, each, half an ounce; peppermint water, three ounces. A dessertspoonful to be taken every three or four hours until ringing in the ears is produced.

THE HARVARD MEDICAL SCHOOL.

The position of dean of this school having been resigned by Dr. H. P. Bowditch, it is said to have been offered to Dr. William M. Richardson, professor of obstetrics. Among the subjects for the evening lectures is the anatomy and surgery of the gall bladder, by Professor Maurice H. Richardson.

ITEMS, ETC.

Pulmonary Consumption and the City Board of Health.

—On the 28th of November Dr. Hermann M. Biggs, the board's chief inspector in pathology, sent the following communication to the Hon. Charles G. Wilson, the president of the board:

The most common and fatal disease which prevails in New York is both contagious and preventable. In 1892 more than six thousand deaths were reported to the New York City Health Department as due to tuberculosis. While this condition of affairs and its great significance has long been recognized by the board of health, owing to various considerations well known to those familiar with tuberculosis, this disease has not up to this time come under the official sanitary surveillance of the department.

In 1889 the board of health requested its pathologists to formulate a brief statement regarding the contagiousness of tuberculosis and the best means for its restriction. In compliance with this request a report on the nature and prevention of tuberculosis was made. The chief purpose of the board then

was the dissemination of the knowledge of the contagiousness of tuberculosis and the education of the people as to the communicable and preventable character of this disease. The report of the pathologists and circulars based upon it, detailing measures of prevention, were then widely published and circulated by the department.

In the *Annual Report of the New York City Health Department* for 1892 you have presented an analysis of the mortality tables of pulmonary diseases, showing the distribution, the ratio of increase and decrease in wards, relation to density of population, etc., of pneumonia, tuberculosis, and bronchitis, which has brought out many important facts regarding the spread of these diseases and especially of tuberculosis, and afforded many suggestions as to their sanitary surveillance and investigation.

The time, it seems to me, has now arrived when it becomes the duty of all sanitary authorities to assume a more aggressive attitude toward this the most widely prevalent and fatal disease to which the human race is subject, and I desire to present to the board for its consideration certain suggestions as to definite means which should at once be taken to prevent and restrict tuberculosis.

It may not be amiss, in order to bring out more forcibly the immediate necessity of such a course, to recount some of the known and now generally accepted facts regarding the nature of this disease. The disease known as tuberculosis may affect any organ or tissue of the body. When it affects the lungs it is called pulmonary tuberculosis, or consumption. In this form it causes about one fourth of all deaths occurring in the human being during adult life, and more than one half of the entire adult population at some time in life acquire it. It has been proved beyond a doubt that a living germ called the tubercle bacillus is the cause and the only cause of tuberculosis. When these germs find their way into the body they may multiply there, if favorable conditions for their growth exist, and produce small new growths or nodules (tubercles) which tend to soften. The discharges from these softened tubercles containing the living germs are thrown off from the body. In pulmonary tuberculosis the expectoration contains the germs, often in enormous numbers. It has been shown that many millions of tubercle bacilli may be discharged, under certain conditions, in the course of twenty-four hours by one person suffering from tuberculosis. The germs thus thrown off do not grow outside the living human or animal body except under artificial conditions, but they may retain their vitality and virulence for long periods, even when thoroughly dried. As tuberculosis can only result from the action of these germs, it follows from what has been said that when the disease is acquired it must result from receiving into the body the living germs that have come from some other human being or animal affected with the disease; in other words, it can not occur except by *direct communication* from some other individual or animal suffering from tuberculosis.

While the meat and milk of tubercular cattle may be important sources of danger, yet the disease is acquired, as a rule, through its communication directly from man to man. The expectoration of tubercular persons frequently lodges in places where it afterward dries, as on handkerchiefs, clothing, carpets, floors, the streets, and so on. After drying, it is very apt, in one way or another, to become pulverized and float in the air as dust. Pulmonary tuberculosis or consumption (the most common form of the disease) is usually produced by breathing air in which the living germs are suspended as dust. It has been shown experimentally that dust collected from the most varied points in hospital wards, asylums, prisons, hotel bedrooms, private houses, etc., where consumptive patients have lived, is capable of producing the disease. Such dust may retain for weeks and even for months its power of causing the

disease, and persons inhaling the air in which this dust is suspended breathe in the living germs. It should, however, be distinctly understood that the breath of tubercular patients and the moist sputum received in proper cups are not elements of danger, but only the dried and pulverized sputum. The breath and moist sputum are free from danger because the germs are not dislodged from moist surfaces by currents of air. If all discharges were destroyed at the time of their exit, by far the greatest danger of communication from man to man would be removed.

It is a well-known fact that some persons, and especially the members of some families, are particularly liable to tuberculosis. So marked and so frequent is the development of the disease in certain families that the affection has long been considered hereditary. We now know that the disease itself is very rarely hereditary, but that there is inherited a liability to the disease which renders the individual an easier prey to the living germs when once they have gained an entrance.

Where the parents are affected with tuberculosis the children, from the earliest moments of life, are exposed to the disease under the most favorable conditions for its transmission, for not only is the dust of the house likely to contain the bacilli, but the relations also between parents and children, especially between mother and child, are of that close and intimate nature especially favorable for transmission by direct contact. The frequent occurrence of several cases of pulmonary tuberculosis in a family is, then, not to be explained on the supposition that the disease itself has been inherited, but that it has been produced after birth by transmission directly from some other individual.

It follows from what has been said that tuberculosis is a communicable—that is, a contagious-germ—disease, and is distinctly preventable. The means which are most certain to prevent its spread from one individual to another are those of scrupulous cleanliness regarding the sputum. These means are largely within the control of the affected individual. It should be constantly kept in mind that it is the sputum and the sputum alone which is commonly the important agent in its transmission.

It is furthermore to be remembered that consumption is not always, or even generally, as was formerly supposed, a fatal disease, but that in a very large proportion of cases, if recognized early, it is a distinctly curable affection. An individual who is well on the road to recovery may, if he does not with the greatest care destroy his sputum, diminish by self-inoculation his chances of recovery.

The following facts should be especially emphasized:

First, tuberculosis is a contagious disease and is distinctly preventable.

Second, it is acquired by the direct transmission of the tubercle bacilli from the sick to the well, usually by means of the dried and pulverized sputum floating as dust in the air.

Third, it can be largely prevented by simple and easily applied measures of cleanliness and disinfection.

The time has arrived when the knowledge concerning the causation, extension, and prevention of pulmonary tuberculosis is sufficiently definite to make possible the adoption of important practical measures for its restriction, yet these measures must at present differ in many respects from the more summary proceedings justified in other more readily transmitted contagious diseases, for it is to be remembered that while tuberculosis is always the result of infection, yet it is far less readily communicated than some contagious diseases, and with proper precautions victims of this disease may, without endangering others, pursue their usual vocations.

I would therefore recommend, first, that there be systematic

ally disseminated among the people, by means of circulars, publications, etc., the knowledge that every tubercular person may be a source of actual danger to his associates, and his own chances of recovery be diminished, if the discharges from the lungs are not immediately destroyed or rendered harmless.

Second, that all public institutions, such as asylums, homes, hospitals, dispensaries, etc., be required to transmit to the board of health the names and addresses of all persons suffering from pulmonary tuberculosis within seven days of the time when such persons first come under observation.

Third, that special inspectors be assigned to duty for the investigation of this disease, and whenever the department has become aware of the existence of families or premises where tuberculosis exists or has recently existed (as in case of death or removal) it shall be the duty of these inspectors to visit such premises and deliver proper circulars and give suitable information to the persons residing there and take such specific measures of disinfection as are required in each case.

Fourth, that the board urge upon hospital authorities the importance of separation, so far as possible, in the hospitals of this city of persons suffering from pulmonary tuberculosis from those affected with other diseases, and urge that proper wards be set apart for the exclusive treatment of this disease.

Fifth, that the Department of Charities and Correction of this city be requested to set apart one of the hospitals under its charge, to be known as "The Consumptive Hospital," to be used for the exclusive treatment of this disease, and that, so far as practicable, all inmates of the institutions under its care suffering from tuberculosis be transferred to this hospital.

Sixth, that the Health Department undertake the bacteriological examination of the sputum for diagnosis in every case of pulmonary disease of doubtful character in hospitals or private dwellings or tenement houses where the physician in attendance desires that this should be done—this procedure to be carried out with a view of obtaining definite knowledge upon which the proper sanitary surveillance of those suffering from tuberculosis can be based.

Seventh, that all physicians practicing their profession in this city be requested to notify this board of all cases of pulmonary tuberculosis coming under their professional care.

For the proper performance of the preliminary work as detailed above, a special corps of medical inspectors and disinfectors should be provided, whose duties should be entirely confined to work connected with the investigation of tuberculosis and the carrying out of the means to be taken for its prevention.

Finally, in urging the adoption of this report, or some similar one, I would add that there is, it seems to me, a widespread feeling among the medical profession and the laity that some efficient means should be taken at once to prevent the great and unnecessary loss of human life caused by consumption, and it is imperative that sanitary authorities adopt such measures as science has shown to be practicable and efficient in controlling the ravages of this disease.

It is my belief that the New York City Board of Health, which has so often achieved notable success in the management and control of other contagious diseases, should take the lead in this matter and adopt measures to meet this new and urgent demand upon its resources.

The New York Academy of Medicine.—The special order for the meeting of Thursday evening, the 7th inst., was a paper by Dr. J. B. Murphy, of Chicago, on various subjects pertaining to abdominal surgery.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 12th inst., Dr. Robert W. Taylor will read a paper on Some Unusual New Growths of the Vulva,

and Dr. E. Fuller will read one entitled The Requirements of a Suspensory Bandage, including Remarks on its Uses and Abuses.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 14th inst., Dr. W. Hallock Park will read a paper entitled Bacteriology: the Present Status of our Knowledge, and Dr. John W. Brannan will read one on The Extent to which the State can Control Infectious Diseases.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 18th inst., Dr. E. S. Peck will read a paper on Operative Interference in Detachment of the Retina, and Dr. Frank Van Fleet will read one on Astigmatism and the Ophthalmometer.

The City (Charity) Hospital.—On Wednesday evening, the 6th inst., the medical board of the hospital gave a dinner at the Savoy Hotel in honor of Dr. Robert W. Taylor, who recently resigned from the board. Dr. Thomas H. Burchard presided.

The Society of Medical Jurisprudence.—At the next meeting, on Monday evening, the 11th inst., Mr. W. A. Short, of the New York bar, will read a paper on Suicide and Evolution.

The Shelby County, Indiana, Medical Society.—At the next meeting, on December 11th, Dr. E. W. Leech will read a paper on Diseases of the Rectum, and Dr. D. F. Randolph will read one on The Hereditary Tendency of Diseases.

The Medical Society of the County of Albany, N. Y.—At the next meeting, on Wednesday, the 13th inst., Dr. F. O. Curtis will read a paper on Certain Points in regard to Eczema, and Dr. H. Hun will read one on The Treatment of Myxædema by Feeding with the Thyroid Gland.

The North Carolina Board of Health.—The board's *Bulletin* for November announces that Dr. John Whitehead, of Salisbury, has been elected a member of that body, in place of Dr. Hodges, formerly of Wilmington, who has left the State.

A Nutritive Enema.—*L'Union médicale* credits Bernheim with the following formula: Milk, ten ounces; the yolks of two eggs; old rum, half an ounce.

A Statue of Ricord, says *L'Union médicale*, has been erected in front of the Hôpital du Midi on a pedestal that has already been some time in place.

Changes of Address.—Dr. Charles N. Dixon Jones, to No. 106 West One-hundred-and-twenty-eighth Street; Dr. Charles I. Pardee, to No. 6 East Forty-third Street; Dr. Albert C. Stanard, to No. 24 West Twenty-fifth Street.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 26 to December 2, 1893:*

STARK, ALEXANDER N., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Clark, Texas, and will report in person to the commanding officer, Fort Sam Houston, Texas, for duty at that post.

Society Meetings for the Coming Week:

MONDAY, December 11th: New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society, New York (private); Society of Medical Jurisprudence, New York; Boston Society for Medical Improvement; Gynaecological Society of Boston; Norwalk, Conn., Medical Society (private); Shelby County, Indiana, Medical Society; Burlington, Vt., Medical and Surgical Club; Baltimore Medical Association.

TUESDAY, December 12th: New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Chemung (quarterly)—Elmira, Oswego (semi-annual)—Oswego, Rensselaer, and Ulster (quarterly), N. Y.; Newark, N. J., and Trenton, N. J. (private), Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Baltimore Gynecological and Obstetrical Society; Practitioners' Club, Richmond, Ky.; Morris, N. J., County Medical Society (semi-annual).

WEDNESDAY, December 13th: New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private); Medical Societies of the Counties of Albany, Cayuga (semi-annual), Cortlandt (semi-annual), and Montgomery, N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

THURSDAY, December 14th: New York Academy of Medicine (Section in Pædiatrics); Brooklyn Pathological Society; New York Laryngological Society (annual); Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia; Northwestern Ohio Medical Association (first day—Toledo).

FRIDAY, December 15th: New York Academy of Medicine (Section in Orthopædic Surgery); Baltimore Clinical Society; Chicago Gynecological Society; Northwestern Ohio Medical Association (second day).

SATURDAY, December 16th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

Meeting of November 1, 1893.

The President, Dr. FREDERICK H. WIGGIN, in the Chair.

Epithelioma of the Tongue.—Dr. PARKER SYMS presented a patient showing the result of operation for this condition. The patient was a man, sixty-eight years of age, who had first noticed a sore on the side of the tongue about six years before which he described as being hard and ulcerated. It had healed several times after his desisting from using cigars. It had, however, remained unhealed from the fall of 1891 until he was first seen by the speaker at the Cancer Hospital early in November, 1892. At this time there had been a hard ulcer about half an inch in diameter, at the left side of the base of the tongue, which had had all the appearances of carcinoma, and the microscope had confirmed this diagnosis. On November 16, 1892, half of the tongue had been excised by Whitehead's method. There had been no recurrence so far, so that the case illustrated very well that when such a growth was situated well forward on the tongue it could be thoroughly removed by this lesser operation. Although this was the first time he had performed this operation, he had found no special difficulty in ligating the vessels and carrying out the various steps of the operation, and had found it much easier than he had been led to believe it. At present there was a small white spot on the cicatrix which at first glance seemed suspicious, but closer examination showed it to be only an abrasion from contact with a sharp tooth.

Successful Case of Cœliotomy for Traumatic Peritonitis; Enterectomy with Circular Enterorrhaphy (Mauless's Method); Exhibition of the Patient and Specimen, and Demonstration of the Method.—The President read a paper with this title. (To be published.)

Dr. CHARLES PHELPS said that he could only speak in approbation of the paper, for few surgical papers presented more of value and novelty than this one. So far as he knew, there were only two recorded cases, the one just reported being the second one of intestinal resection in which Mauless's method had been adopted in New York or its vicinity. The first operation had been done by another member of this society, Dr. Hartley. The cumbersome and tedious methods hitherto employed had rendered the usual operation of intestinal resection very uncertain in its results; hence an operation which could be performed with so much rapidity and ease must be regarded as an exceedingly agreeable surgical revelation. Personally, he thought that no other device was likely to supersede this new operation. With this method at his disposal, he would now be willing to operate on many cases where formerly he would have hesitated or refused to operate.

The use of peroxide of hydrogen in the peritoneal cavity and leaving this cavity filled with hot salt solution he believed to be new points in the technique. The knowledge that one could successfully use the peroxide of hydrogen in this way made the prospect of success much better, and the leaving of the hot solution he thought, from theoretical considerations, must prove an effectual measure for the treatment of shock. Intestinal resection was a much more facile and a much more promising operation than it had been heretofore.

Dr. FREDERICK S. DENNIS said that he had been much interested in the paper and in the case, which he had seen before from time to time. So far as he knew, there had been only one case besides the author's in which a diagnosis of rupture of the gut had been made, and laparotomy with end-to-end suture of the gut after resection performed; hence Dr. Wiggins should be warmly congratulated on the success of so brilliant an operation.

There was another point of interest in the case—namely, that the patient had come to this city with a large ulcerating tumor at the verge of the anus which had looked very much like an epithelioma, but, on examination, had been found to be a condyloma. This the speaker had removed by the application of an ordinary elastic band, a procedure described by the late Dr. Nathan Smith, of Baltimore. The mass had been, without exaggeration, of the size of one's fist, and bleeding, ulcerating, and foul. In less than twenty-four hours after the application of the elastic ligature around the pedicle of this mass it had sloughed off, and had now entirely disappeared, although only five or six days had elapsed since the operation.

Dr. J. W. S. GORLEY thought that Dr. Wiggins should be congratulated upon the success of this case, which was owing, first, to the early surgical interference, and, secondly, to the measures adopted in the after-treatment. With respect to the first, he would say that there was usually too much delay; even in this case the operation might have been performed many hours sooner.

This method of operation, which he had seen Dr. Wiggins demonstrate before, impressed him very favorably. It had been objected that the longitudinal incision of the intestine below was an unnecessary complication; but since such a wound could be so easily closed, and since any flatus would be apt to collect above, the objection did not seem to him to be valid. The absolute peritoneal contact secured by this method of suture seemed likely to render the end-to-end operation safer than even the Murphy button. The latter might become a very dan-

gerous foreign body in the intestine, although it was a very pretty operation, and was even more quickly performed than Maunsell's.

He had been greatly interested in the washing out of the peritoneal cavity with peroxide of hydrogen; he was glad to know that the peritoneal cavity would tolerate this agent so well. It was well borne by connective tissue, and tolerably well by the buccal membrane, even when used in its pure state; but certain other mucous membranes, such as those of the bladder and urethra, did not tolerate it. Such rapid oxidation was produced that the pain was unbearable—worse even than that produced by the use of strong solutions of bichloride of mercury.

The filling of the abdominal cavity with warm salt solution had been resorted to two years ago in this city by Dr. Baldwin in a case of abdominal section for a very large uterine myoma—a tumor at least six inches in diameter and almost globular. The operation had been difficult and tedious, and the patient had been in collapse, so the operator filled the abdominal cavity with as much very hot Thiersch's solution as it would hold. He had looked upon this as a very important factor in the recovery of his patient, and he had thought the large volume of the fluid, as well as its heat, was important.

The author of the paper had also introduced another very important point which could not be too often repeated, and that was that as little time as possible should be lost in the performance of abdominal operations. It was a potent element of success. Every year, every month, almost every week, did his dread of ether increase, especially in connection with the way in which it was given in our large hospitals, such as Bellevue. In private practice among healthy subjects it was perfectly safe. He had had very few deaths from ether, but he could never forget the first case. It had occurred at the time when Dr. Polk was house physician, and, he thought, Dr. Bryant was house surgeon—as far back as 1870. The patient had been brought to the hospital with luxation of the hip. He was a stalwart but drunken fellow. He had first been placed on the table and the usual quantity of ether given. Attempts had been made by several surgeons to reduce the dislocation of the hip, but these had failed. Then some of the medical staff had tried, and had also failed. The man had then been put to bed for two days, and at the end of this time he had again been etherized. The speaker had tried, then the house surgeon had tried, and then Dr. Smith and Dr. Sayre, but all had failed. There had been almost total suppression of urine following this etherization, and two days later the man had died. The autopsy had shown the contracted kidney so commonly found among drunkards. Ever since that time he had been afraid of ether. In private practice he had given as little as possible, sometimes giving chloroform to young subjects, but as far as possible using the nitrous oxide. Many years ago Dr. James R. Wood had used it in an amputation of the thigh, but his apparatus had been cumbersome, and the method had not been generally adopted. In the last few years, in nineteen out of twenty cases, he had used nitrous oxide in preference to ether, on account of the evil effects which many had observed from ether.

Dr. W. R. TOWNSEND said that he had had the pleasure of listening recently to a paper on peroxide of hydrogen as a hæmostatic in cases of epistaxis. The author had found it even better than plugging of the nostrils. In the discussion of this paper several others had spoken of having had good results from it in this direction. In view of this, it might be that peroxide of hydrogen would prove especially useful where there was troublesome oozing in the abdominal or pelvic cavity. Certain experiments which he understood were now being carried on by Professor Thompson, of the University, went to show

that peroxide of hydrogen had a special tendency to produce coagulation of the blood, both in the veins and in the arteries.

Dr. W. EVELYN PORTER said that he was inclined to believe that if the peroxide of hydrogen had been used with only simple water irrigation it would have caused irritation, and even adhesions. On this account, in advocating its use, it would be wise to recommend in every case that the cavity should subsequently be irrigated with normal salt solution. He believed this should be used very generally in abdominal work, not only in acute cases, but in the more chronic ones, especially those found in women.

He thought that, in addition to Maunsell's method, the use of a single row of sutures, either continuous, or Lembert's interrupted sutures, around the outer layer, uniting the peritoneal surfaces, would be a very great safeguard, as we all knew in any case of intestinal suture unless there was very little distention there was apt to be leakage of the contents of the bowel. He did not like the form of ether inhaler exhibited and recommended by the author. One modified by Dr. Wyeth, with an opening for entrance of air, he considered very much better.

Dr. R. A. MURRAY said he thought that the fatal result in these cases was due most often to delay in operating, and this delay occurred usually because the profession at large believed that if there was any septic trouble in the abdomen, there was always high temperature, pulse, and respiration. This was a very great mistake. We should call the attention of the profession generally to the fact that more was to be learned from the facial appearance and the condition of shock than from the temperature, pulse, and respiration. For instance, two weeks before he had had a patient with irreducible crural hernia. Two days before he had seen her this time she had complained of moderate pain, and as she had been warned about this pain, she had immediately applied an ice bag and had sent for him the next day. She had vomited once, but the matter ejected had not been greenish; the abdomen had been flat; the pulse had been 72 and the temperature normal. The next day she had vomited once; the abdomen had been flat; there had been no impulse in the tumor, although there had been a slight impulse on the previous day; the pulse had been 72, and the temperature had been still normal. The patient had been informed that the hernia was strangulated and that an operation was necessary. The case had then been transferred to the New York Hospital, and that evening there had been still no change in the pulse and temperature, but there had been a peculiar facial expression and a smallness of the pulse which was suggestive. There had been some very slight pain. Dr. Bull had operated and had found six inches of the gut strangulated and almost black, and the sac filled with bloody fluid. He had seen puerperal septic peritonitis with almost no rise of temperature, yet with a small pulse. He believed that a wiry pulse, even though slow, the condition of shock, and the facial expression were better guides than the thermometer—in fact, the thermometer was quite misleading. If we waited for the occurrence of abdominal distention, the result was almost always fatal.

Dr. SYMS thought the case reported in the paper should be considered as one of the triumphs of modern surgery, and he hoped it would lead to very many more cases of this kind being recorded. He thought that most surgeons now agreed that the existence of peritonitis was an indication for operation. About three weeks ago he had made an appointment to operate on a case which he had diagnosed as probably tubercular peritonitis. To his surprise, a consultant had advised waiting because there had been evidently peritonitis present, and he had looked upon this as an indication against instead of for an operation.

Perhaps the most important part of the paper was the calling attention to the necessity for an early diagnosis of peritonitis in cases where there was injury to the abdomen without external marks of violence. Perhaps, as the preceding speaker had said, the pulse was the most important sign; certainly the temperature was no guide whatever. In some cases which he had seen the advance of the peritonitis had been announced by a fall of temperature below the normal. The facial expression was fully as important as the pulse—perhaps even more important. The symptom of hæmorrhage from the intestinal tract which had been present in the author's case would seem to indicate injury to the intestine, and this should in itself be sufficient to indicate the necessity for at least an exploratory operation. He had no doubt that Maunsell's method of intestinal suture was the method of the present and the future. Intestinal anastomosis by means of Senn's plates and their various modifications had been almost abandoned; it was very difficult, and required special apparatus which was not always readily obtainable. Moreover, the lateral anastomosis was an unnatural method of joining divided intestine, and the contraction which took place threatened the patient with intestinal obstruction. At post-mortem examination he had seen this contraction so great that a pencil could hardly be passed through the aperture left in the intestine. Maunsell's method produced such perfect coaptation of the peritonæum that it seemed hardly possible to excel it. The suggestion of Dr. Porter to make an overhand Lembert suture after the Maunsell suture had been made seemed to him an excellent one. In the first case of operation here by Maunsell's method—Hartley's—he believed this plan had been adopted. The portion of suture which was most difficult to make perfect and where most end-to-end sutures had failed was at the intestino-mesenteric junction, and this was the portion especially well closed by Maunsell's method.

About the time of the author's operation he had done the same operation for carcinoma. A Kraske operation had been attempted for the removal of the carcinoma, but the conditions had been such that the tumor could not be reached posteriorly, the adhesions being too dense and the tumor too high up. It had therefore been considered advisable to perform laparotomy, so this resection by Maunsell's method had been done subsequently when the patient had rallied sufficiently from the first operation. The man had done very well for a few days, but had suddenly developed an extensive slough at the seat of the Kraske operation, which had infected the entire posterior wound, and he had died of sepsis. There had been much shock at the termination of the operation, so the abdomen had been filled with hot normal salt solution with very excellent results as to the immediate improvement in his condition. He regarded it as nearly equal to infusion.

The care necessary in the administration of ether was a very important element of success in all operations. These abdominal operations should be done as speedily as possible. This was one of the great advantages of Maunsell's method, for with good assistance it could be completed in twenty minutes.

Dr. SYMS exhibited an ether inhaler which he had had made and which he considered more convenient than the other inhaler shown by Dr. Wiggin.

Dr. M. D. FIELD said that some years ago a man had been injured on the elevated railroad by a "buffer accident." He had made his way from New York city to Brooklyn, walking altogether several blocks without assistance. The accident had occurred on Sunday afternoon, but nothing serious had been observed until Wednesday morning, when he had been taken with stercoraceous vomiting. A diagnosis of intussusception had been made after a hasty consultation and injection *per rectum* had been attempted. The speaker had arrived just

after this had been done, and had found the patient in collapse. He had died shortly afterward. The autopsy had shown that the man had received a wound across the abdomen, and although there had never been anything more than a slight discoloration on the skin, the areolar tissue had been severed. On opening the abdomen, it had been found that the mesentery had been torn away for nearly half an inch, and that gangrene had resulted in nearly two feet of intestine. This evidently had accounted for the inaction of the bowels and the stercoraceous vomiting. In addition to this, the intestine had been found to have been torn in three places, and every one of those wounds had healed, and there was nothing in the abdomen which had not been absorbed except a little of the injection fluid which was found on one side nearest to the lowest wound in the intestine. He would have recovered from the three lacerations of the intestine had it not been that they were complicated by tearing up of the mesentery, which had caused gangrene of the intestine.

The PRESIDENT said that he agreed fully with Dr. Gouley that the operation should have been done earlier; it should have been done the first night he saw the patient. When he had first seen him he was seven or eight miles from his office, with many other engagements which would have made it impossible for him to operate for a number of hours. A medical student, who was living in the house, had been asked to report the patient's condition to him. Receiving word over the telephone subsequently that the patient was "all right," he did not see the boy until the following evening.

He had used the peroxide of hydrogen three times in laparotomies where patients had recovered, and there had been no sign whatever of intestinal obstruction or of inflammation. The first case had been that of an old lady upon whom he had operated in September for purulent ovarian cyst. The tumor had filled the pelvis, and had reached half way to the umbilicus. The fluid could not be removed by simple tapping, and in breaking up the adhesions with the hand, some of the remaining contents had burst through the sac at a weak point. The peroxide of hydrogen had been immediately poured in, and allowed to remain for some time. The tumor had then been removed and the cavity flooded with hot salt solution. The temperature had never risen above 100°.

About a week after the operation described in the paper he had operated on a case of pyosalpinx following abortion. The case had been rather septic, the temperature varying between 101° and 102.5° F. In breaking up the adhesions surrounding the ovary, the sac had been ruptured. Here also the peroxide of hydrogen and saline solutions had been used. The temperature had reached normal forty hours after the operation. There had been no trouble with the movements of the bowels in these cases; in fact, he found that the bowels usually moved earlier after the saline solution had been used. The use of morphine was desirable, and this he thought could be safely done when the salt solution had been employed, because this counteracted the tendency to constipation.

He did not think it necessary to use the additional row of sutures; he thought there was some danger of strangulating the circulation through the intestine. This was the great danger in the first operations of end-to-end suture where a double row of sutures was used. In his case an eighth to a quarter of a grain of morphine had been given every three hours to prevent a movement of the bowels, yet they had moved repeatedly in the course of the first few days.

He had been much interested in the remarks of Dr. Murray about the misleading character of some of the symptoms. He thought that temperature was no guide at all; the pulse and facial expression were the real guides to the diagnosis.

A Method of Rhinoplasty.—Dr. PARKER SYMS read a paper on this subject. (To be published.)

Dr. GOULEY said that he wished to speak of a method of relieving deformity of the nose resulting from injury. In 1866 a prize fighter had appeared at his clinic who had lost the ala of his nose on the left side, a man having bitten off at least three fourths of it. There had been only a little cicatricial substance left. He had adopted a very simple method of relieving the deformity—viz., excising the cicatricial tissue so as to make a long V-shaped cut and then twisting the end of the nose down and attaching the two edges of the V-shaped gap by interrupted sutures. Primary union had taken place. The nasal surface had been a little smaller at first on that side, but after a few weeks the nose had become very nearly straight. A few months later a woman had come to him with a similar deformity, a portion of her nose having been bitten off. A good result had been obtained in her case from the same operation. In these cases the flap was usually taken from the cheek, and this often left a very considerable scar on the cheek, and the edge could not be as well modeled. This very simple procedure might be applied in the majority of cases.

He agreed with the reader of the paper that an artificial nose was preferable to any of the usual methods of rhinoplasty which were employed in cases of destruction of the bony framework of the nose. In the memorable case treated by Dr. Sabine, where the finger had been fastened to the face in place of the nose, it had been perfectly evident that it was a finger and not a nose. These artificial noses very closely imitated the natural organ. He recalled a case in which a man who had been fitted with an artificial nose had provided himself with several noses—for instance, a blue nose for cold winter weather.

Dr. PORTER said that there was one difficulty in the operation described in the paper, and that was that when the greater part of the nose had been removed there was no notch left; hence it was wise to nick the flap and allow it to heal up by granulation, as the contraction which occurred during healing produced the desired depression. Another difficulty was that the flap in contracting drove the nose more to one side than the lateral flap-sliding operation. With the latter method, however, there was danger of sloughing.

Dr. SYMS said that all surgeons who had had experience in this method of operating appreciated the difficulty of obtaining the necessary depression at the side of the nose. In one case he had left in a drainage-tube during the healing process, and a loop-suture had been passed completely through the nose and septum so as to hold the flap down tightly to the cheek. It had helped a little, but where there was any extensive repair to the nose to be done, the result was always poor, and the proper thing was to cover up the gap with as good a nose as possible by the simplest form of operation.

SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

Sixth Annual Meeting, held in New Orleans, November 14, 15, and 16, 1893.

The President, Dr. BEDFORD BROWN, of Alexandria, Va., in the Chair.

The Diagnosis of Pelvic Inflammatory Diseases.—A paper thus entitled was read by Dr. HOWARD A. KELLY, of Baltimore. He called attention to certain common sources of error in making diagnoses of pelvic inflammation. An erroneous conclusion was often reached in these cases, both by the general practitioner and by the specialist, by relying for the diagnosis upon such symptoms as dysmenorrhœa, more or less persistent pain in the pelvis, attacks of pain confining the pa-

tient to bed, diagnosed as peritonitis, difficult locomotion, cachexia (due to the morphine habit), tenderness on pressure over the ovarian region, and extreme tenderness at the vault on vaginal examination. Such a group of symptoms frequently characterized a false or pseudo-pelvo-peritonitis, in which there was actually no demonstrable lesion of any pelvic organ.

In order to make a diagnosis of true pelvic inflammatory disease, the inflamed structures must be examined directly by touch. The various subjective symptoms must be regarded as of secondary importance in reaching a diagnosis. Even the patient's observation that she had passed a quantity of pus could not be relied upon unless the pus was seen by the physician, as patients often mistook muco-purulent discharges from the uterus for the emptying of an abscess. Fever, and especially recurrent attacks of fever, were valuable aids in making the diagnosis, but fever was generally absent, even in abscesses, when the pus was encapsulated.

The direct examination, the sole test, was to be made by the vagina, or by the vagina and the lower part of the abdominal wall, and the diagnosis of pelvic inflammatory disease was made when a definite hard resisting mass was felt on one or both sides of the cervix. Through an empty rectum these masses were still more distinctly outlined. When the disease was not quite so evident a bimanual examination through the rectum and abdomen should be made, carrying the index finger of the lower hand above the rectal pouch behind the uterus and laterally out on to the broad ligaments. The most minutely accurate examination of the pelvic organs which could possibly be made was called for when the ovaries and tubes were inclosed in delicate bands of adhesions which allowed considerable mobility to structures not enlarged. This was accomplished by the tri-manual method by the vagina, the rectum, and the abdomen simultaneously, under anaesthesia. (See Dr. Kelly's article in the *Journal* for November 25th.)

The Conservative Treatment of Pyosalpinx.—Dr. C. KOLLOCK, of Cheraw, S. C., followed with a paper thus entitled. He said that in cases of pyosalpinx much caution and a very careful and rigid examination were called for to determine the cause of the presence of pus, the length of time it had been there, and the condition of the walls of the tube in which it was found. Attention should also be given to the peritonæum and the ovaries, but, above all, there should be the strictest inspection of the endometrium, a disordered condition of which contributed much to the production and continuance of pus in the tubes.

Within a year or two changes had been made in the treatment of pyosalpinx, and conservatism now entered largely into its management. Men of high position in the profession were more decidedly agreed that a moral obligation rested upon us to relieve patients without the sacrifice of any organ, or part of one, when this was compatible with safety. Recently Polk, Pryor, Krug, Boldt, and Dudley had reported to the New York Obstetrical Society a number of cases of pyosalpinx treated by the conservative method now in vogue. This treatment, when faithfully carried out by curetting and aseptic division, had not only been successful in saving the tube and ovary on the non-affected side, but in several instances the diseased tube had been entirely relieved of the presence of pus. That many cases of pyosalpinx had been accurately diagnosed and radically cured without the mutilation of any part of the sexual organs was well authenticated. Dr. Kollock's experience, while limited compared to that of others, had been sufficient to convince him that the conservative system of practice was bringing us to that period when the mutilation of women, once supposed to be necessary, should cease.

Dr. Kollock then reported a few cases of pyosalpinx which

had fallen into his hands, the happy termination of which had placed him under obligations to the pioneers in the conservative treatment. All but one of four patients had been relieved entirely without resorting to oöectomy.

Dr. GEORGE J. ENGELMANN, of St. Louis, emphasized the importance of administering an anæsthetic in examining patients with pelvic inflammatory disease before serious operative procedures were entered upon. It was not alone the anæsthetic, however, but the practiced touch.

Dr. JOSEPH PRICE, of Philadelphia, alluded to dropsical tubes as being a group of cases that puzzled the practitioner from a diagnostic point of view and afterward surgically. Angry pus cases, while acute in their early history, were simply cases to be dealt with surgically. The attacks of pain were numerous, and fixation and tenderness were characteristic symptoms. Everything in the pelvis was board-like, and when the surgeon opened the abdomen from above it was difficult to distinguish the uterus from the appendages, and *vice versa*. These were trying cases to deal with.

Dr. JOHN D. S. DAVIS, of Birmingham, Ala., said he was in favor of evacuating pus wherever it was found in the body. There were, however, some cases in which pus could be removed without sacrificing the ovaries or tubes. As to the use of an anæsthetic, he considered it absolutely essential in the examination of doubtful cases, but where the diagnosis was plain it was not necessary.

Dr. R. B. MAURY, of Memphis, said the great difficulty in the class of cases referred to by Dr. Kollock, in which there was pelvic inflammation associated with muco-purulent discharges from the uterine cavity, was to decide whether there was pyosalpinx. There was what was denominated endometritis, associated with it normal discharges and exudation in the pelvis, but Dr. Maury said he was at a loss sometimes with the most careful diagnostic measures, whether under ether or without it, to form in his own mind an accurate picture of what the precise state of things was in the pelvis. The rule he had laid down in the treatment of such cases was, if they were acute, non-puerperal or puerperal, that the woman was entitled to a certain period of rest and other measures non-surgical before deciding upon a radical operation.

Dr. W. E. B. DAVIS, of Birmingham, Ala., believed that in the examination of patients it was exceedingly difficult in some cases to make an accurate diagnosis without an anæsthetic. However, there were women who could stand the examination well without it. In regard to endometritis, by judicious and careful ennetting he believed many patients could be saved the necessity of an abdominal section. The trouble was that practitioners often denounced one procedure and upheld another without outlining the indications for a certain position. It was very important to cure the endometritis before it spread to the tubes.

Dr. R. M. CUNNINGHAM, of Pratt City, Ala., was inclined to look upon endometritis in the vast majority of cases of disease of the appendages as the *fons et origo* of the whole affair, and he believed that the operation which had been systematized and popularized by Dr. Polk was a safe, conservative, and reliable procedure. Furthermore, in the hands of the general practitioner it would relieve many patients that now went to the laparotomist.

The PRESIDENT said the mobility of the uterus and its fixation were questions of great importance in diagnosing pelvic inflammatory disease.

A Memorial Address on Dr. Ephraim McDowell was delivered by Dr. L. S. McMURTRY, of Louisville. He said it would seem almost a work of supererogation to submit an elaborate biographical sketch of McDowell after the very complete ac-

counts of his life and labors which had been contributed to medical literature by the late Professor Samuel D. Gross and the late Dr. John D. Jackson; yet he presumed that no one would for a moment question the good taste and wisdom of perpetuating in the volumes of *Transactions* of the association the names and deeds of eminent Southern surgeons who had done so much to lay the foundation in America and the whole world for the present splendid system of surgery and gynecology. This galaxy of illustrious names would be incomplete without McDowell's, the father of ovariotomy and the pioneer of abdominal surgery, which in modern times had grown to such grand proportions.

In the year 1852, twenty-two years after the death of McDowell, Professor Gross, in his celebrated *Report on Kentucky Surgery* to the Kentucky State Medical Society, had presented a sketch of the life of this eminent surgeon, with a detailed account of his original surgical work. This sketch had subsequently been incorporated in Gross's *American Medical Biography*, published in 1861.

After giving a sketch of Dr. McDowell's life, Dr. McMURTRY referred to his first ovariotomy, on Mrs. Crawford, and noted some points with reference to his operative technique. The operation in this case had been done without an anæsthetic. The incision was made to the left of the median line, about three inches external to the rectus muscle, and was nine inches in length. After opening the peritonæum he first tied the pedicle with a strong ligature, and then cut open the tumor and removed its contents. He then divided the pedicle, which had previously been tied, and removed the sac. As soon as the incision was made into the abdomen, he stated, the intestines rushed out upon the table and were not replaced until the operation was completed, which, he added, "occupied twenty-five minutes." He then turned the patient upon the left side to allow all fluids to escape. He closed the incision with interrupted sutures and brought out the ligature attached to the pedicle at the lower angle of the wound.

In reporting his cases he had omitted mention of the material composing the ligature, and Dr. McMURTRY had been informed by a friend of McDowell's, now dead, who had been a great deal about McDowell's office in his boyhood, that the ligatures used were made of shoemaker's thread and waxed thoroughly before being used. Adhesive strips and bandages completed the dressing, and, in the author's language, he prescribed "a strict observance of the antiphlogistic regimen." The special features of the technique were: 1. The incision was made through the muscular layer of the abdominal wall three inches external to the rectus muscle. 2. The cyst was not evacuated until after the pedicle was tied. 3. An effort was made to cleanse the peritonæum of fluids. 4. Drainage was aimed at, as well as the escape of the ligatures, by bringing the latter out at the lower angle of the incision. 5. The operation occupied only twenty-five minutes, expedition being more the result, doubtless, of the want of an anæsthetic than of anything else.

In his report of his second case he had used this language: "I laid her side open." In his third case, however, he had adopted the median incision, saying in his report of this case, "I changed my place of opening to the linea alba." In all his cases he had ligated the pedicle before separating the adhesions or tapping the tumor. In his third case he had mentioned that the ligatures could not be released for five weeks, at the end of which time the cord had been taken away.

The Incision in Abdominal Section; How to Close it; Post-operative Complications about it.—Dr. JOSEPH PRICE, of Philadelphia, read a paper on this subject. He said the question that most vitally concerned surgical and gynecological

work was, How could the mortality be reduced? Surgical judgment and surgical fingers constantly determined the issue of life or death.

The Incision.—There was nothing from which one could ever approximately determine to what extent the length of the incision influenced the mortality. The statistics of comparative results would not prove satisfactory, for the reason that so many other compromising elements were entered—adhesions, their character, extent, and locality. That the incision exercised a greater influence than was generally recognized or admitted, he entertained little doubt. As to length, no rule of mathematical certainty could be laid down. In his own experience he found the union of convenience and safety to lie with the short incision. The short incision narrowed the limits of hemorrhage. It was safe to begin with a small incision, and where the size and character of the tumor or the presence of complications required a longer one, it could easily be made. Very much abdominal work could be done through an opening that would admit only two fingers. The reliance of the abdominal surgeon must be largely on educated fingers. In the majority of cases an operation could be done through a small incision without the viscera being seen by the spectators or the operator. Tumors that were adherent throughout, also irreducible or solid tumors, required a long incision for their removal and for dealing with complications. In the majority of cases to so enlarge the opening as to obtain a view of the parts, we augmented the risk of ventral hernia and provoked tediousness of convalescence.

The importance of a perfect closure of the incision had only recently received the attention it deserved. The effort should be to approximate as nearly as possible to normal conditions, dealing with all existing or possible complications with scrupulous minuteness and care, thus guarding against accidents. He would not profess to suggest uniform procedures to be carried out in all cases, as each operator had his own way and did his own work best in that way, and it would not be possible for him to apply others' methods safely and successfully without special training. The author was satisfied that exposure and manipulation of the incised parts, as well as of the peritonæum, were harmful. Incisions bathed in pus and filth and freely manipulated often failed to unite. Suppuration of a wound was largely due to careless closure or to tight sutures, including too much tissue. Tight suturing was too common, and had destroyed life in many feeble subjects. Suppuration due to tight suturing, also stitch-hole abscesses, where they did not result fatally, prolonged convalescence. Cases were cited in point.

Through-and-through suturing, including all the structures—more of the central structure than of the skin or peritonæum—with either silkworm gut or pure silk, gave the most satisfactory results. Silkworm gut seemed to be the favorite material at present, as it possessed all the natural and essential qualities of a suture; it was small, strong, and non-irritating—the three cardinal virtues of all good suturing material. Terracing sutures had nothing to recommend it; on the other hand, the author believed it prolonged an operation. Retraction of the skin and peritonæum by the introduction of silkworm sutures brought about inclusion of more of the central structures and the least possible tension on the skin and peritonæum. Keith, Tait, and Bantock all used a fine straight needle, and their work had been about perfect. The use of large, curved cutting needles was harmful, for it primarily favored hemorrhage and secondarily stitch-hole abscesses.

Dr. KELLY thought that long incisions had little or nothing to do with the mortality except in an indirect way. Where there were many adhesions a long incision was necessary. Handling of the viscera in pre-antiseptic days had increased

the chances of suppuration, and consequently of peritonitis and death. The chances of infection, he believed, were greater with a long incision. Hernia came from improper closure of the abdominal wall or the use of the drainage-tube, causing weakness of the abdominal wall at one point.

Dr. L. S. McMURTRY, of Louisville, demonstrated on the board his method of suturing. He brought peritonæum to peritonæum, muscular structure to muscular structure, fascia to fascia, and skin to skin, and said that the least quantity of interposing material there was between the tissues that were to be brought together the better. He could not agree with Dr. Kelly that the drainage-tube was the cause of hernia after closing the incision.

Dr. R. B. MAURY, of Memphis, favored the silkworm-gut suture. His experience covered nearly three hundred sections, and he had simply used the through-and-through suture. He had observed hardly any abscesses and the smallest possible number of hernias; the latter, he said, could be counted on the fingers of one hand.

Dr. T. J. CROFFORD, of Memphis, said it was considered that all hernias resulting from abdominal section were due to failure to get union between the opposing layers of the transversalis fascia. He used a long curved needle instead of a straight one. With it he could put in stitches in one third of the time he could with the ordinary needle. He had used it in upward of two hundred sections, and had not had a case of hernia follow one of them. He had also had the smallest number of stitch abscesses.

Dr. PRICE said there had been an immense amount of theory about the matter of long and short incisions, and there had been a tendency on the part of some to brush aside pre-antiseptic work. Notwithstanding this, however, some of the older surgeons had had as good results in their day as were obtained in some of our hospitals at present. He urged great caution in the terracing method of suturing.

Is Operation demanded in all Cases of Appendicitis? The Best Time to Operate.—This paper was read by Dr. A. M. CARTLEDGE, of Louisville. He said that inflammatory conditions of the appendix were essentially intraperitoneal lesions. Modern surgeons had an abiding faith in the surgical maxim that whenever pus was believed to be present in tissues or organs of the body, it should be removed; hence the new pathology of a very old and frequently fatal malady inspired surgeons to attempt some radical means of relief. Perfection in technique could come only from individual experience and a knowledge of the work of others.

The pathology of a disease was the only true keynote of its rational treatment. Probably the best classification of appendicitis was catarrhal (simple), ulcerative (from tuberculosis from foreign bodies), and perforating (from ulcerative perforation from strangulation, the result of twisting). This classification dealt strictly with the changes occurring in the appendix, and should be considered apart from the peritoneal and other conditions which might ensue and cause well-marked variations in the clinical course of the disease. If the walls of the appendix gave way in a mass of fibrous adhesions, the result of long-continued irritation, the pus which formed was rather securely encapsulated and might be days, weeks, even years in finding an outlet. In fact, as was often the case, if the *Bacillus coli communis* predominated and a few staphylococci were present, it might remain encapsulated unless it received a new impetus of irritation. Cases had been reported illustrating this point. Cases had also been reported illustrating the part played by injury as an exciting cause in appendicitis, and the belief had been expressed that a chronic form of unrecognized appendicitis had existed prior to such injury.

We knew more about the pathology of ulcerative or suppurative appendicitis than we did of the catarrhal form, because the patients not operated upon who recovered mostly had the form called catarrhal. These were cases which progressed with little pain, with very little fever, 101° F. as a maximum, in which the tumor subsided. These cases were the pride of the poultice-and-opium practitioner. Ulcerative appendicitis must be either tuberculous or traumatic, the trauma being due to foreign bodies or enteroliths, usually the latter. The tuberculous cases would give rise to acute symptoms only as the result of cicatrization and stenosis, with distal distention, or secondary inflammation with pyogenic organisms. Either of these results favored perforation. This was essentially the chronic variety, but it would eventually lead to perforation, probably in the ways indicated.

When physicians came to view inflammations of the vermiform appendix in their proper light, the author said, the prognosis would assume a very different shade. We should consider any appendix once so affected as to deserve the name of appendicitis, whether from tubercle or from trauma, a lastingly diseased structure, and the fancied cures were quiescent states, the results of conditions very easily recognized. If we could trace our so-called first attack cases of appendicitis through subsequent ones, we should say the progress, not only as to health and comfort but as to life, was bad—very bad. A man had the trouble three, four, or five times, apparently recovered, and all the attacks were probably counted as cures by different physicians. Finally he died in an attack; the death was counted but once, and sometimes not then; for if, as was often the case, death resulted from the rupture of an unrecognized appendicular abscess, or from diffuse peritonitis after perforation, the chances were that the cause was never suspected and the death was recorded as occurring from peritonitis. Every case of appendicitis not barred by surgical limitation should be the subject of operation. The best time, provided the symptoms were not too urgent, was after the bowels had been thoroughly moved.

Dr. JOSEPH PRICE agreed with the author of the paper that there was but one treatment for appendicitis—namely, removal of the appendix. He considered it a murderous disease, to be classed with extra-uterine pregnancy. Both demanded prompt surgical treatment when first discovered. He recommended in acute cases of appendicitis, without pus, removal of the appendix and freeing of the inflammatory adhesions.

Dr. G. W. LONG, of Richmond, opposed indiscriminate operations in appendicitis. Autopsies had shown that one third of the human race had had this disease at some period of their lives. That being true, and considering the small percentage of deaths, it naturally followed that appendicitis did not always kill, even if the patient was not operated on. In the catarrhal form, he thought there was no reason for operating. In the perforative form we should operate. In the perforative form without adhesions we should also operate as soon as we made a diagnosis.

Dr. WILLIAM T. BRIGGS, of Nashville, had been operating in every case of appendicitis that came into his hands where the diagnosis was clearly established, and he had had no occasion to regret it. He had operated in cases where there were perforative symptoms and in others where there were none, in some where there was and in others where there was not suppuration, and in still others where there was and where there was not sloughing.

Dr. C. KOLLOCK, of Cheraw, S. C., had seen a great many cases of appendicitis. He recommended saline treatment in the first attack, but if there was a recurrence he invariably operated and had never lost a patient.

Dr. W. E. B. DAVIS, of Birmingham, Ala., had never operated in one of these cases without advising a secondary operation for removal of the appendix, telling the patient that the disease would recur. He thought, however, there were many patients that got well without operation, but it was a difficult matter to tell in what cases we should not operate.

Dr. HUNTER MCGUIRE, of Richmond, said he had many a time operated too late, but never in his life had he operated too soon. If, after free and full purgation with salts, administered by the mouth and by the rectum, the symptoms were not relieved, he thought the time for operation had come, and did not hesitate to operate. He had never known the mere operation, in the hands of skillful surgeons, to kill or add to the danger to the patient's life. Appendicitis killed, and it was put down to inflammation of the bowels, peritonitis, or something else.

Dr. WILLIS F. WESTMORELAND, of Atlanta, favored early operative interference. He had never been called in sufficiently early by the general practitioner to operate, consequently the patients had died promptly. It was necessary to educate the general practitioner to send patients to the surgeon for operation earlier.

Dr. W. B. ROGERS, of Memphis, had seen cases of catarrhal, ulcerative, and gangrenous appendicitis, but had never been able to make a diagnosis until he had opened the abdomen. The symptoms of the disease were the same as those of peritonitis, localized at the site of the appendix. In the cases in which he had operated he was satisfied that no medicine would have effected a cure.

Dr. CUNNINGHAM agreed with Dr. McGuire that an operation should be done in case medical treatment failed to afford relief.

Dr. RIGGS, of Birmingham, advocated operation during the interval between attacks in the recurrent form of the disease.

Dr. JAMES A. GOGGANS, of Alexander City, Ala., had operated early in seven cases, and all the patients had recovered.

Intracranial Neurectomy and Removal of the Gasserian Ganglion for Intractable Neuralgia, with Report of Cases.

—Dr. LOUIS MCLEANE TIFFANY, of Baltimore, read a paper thus entitled. Within the past few years intracranial excision of portions of the fifth nerve, together with more or less complete removal of the Gasserian ganglion, had been done for the cure of intractable trigeminal neuralgia. The credit of first doing such an operation rested with Rose, of London, after whom were to be mentioned Novaro, Horsley, Andrews, and others. Dr. Tiffany then gave an account of Hartley's method, which had been described in the *Annals of Surgery* for May, 1893.

It had been Dr. Tiffany's fortune to operate four times by excision of intracranial portions of the fifth nerve. In each case the reason for the operation had been trigeminal neuralgia not due to disease of the brain. Hartley's method had been followed. All the patients had recovered from the operation and been relieved of neuralgia—permanently it was to be hoped.

The operations had been long, but recovery in each instance had been rapid and complete. In all cases the wounds had healed at once, except in the fourth case, where the patient had scratched the recent wound and infected it.

It was worthy of note that in the case of the patient upon whom the operation had been performed fourteen months before, there was less anesthesia and more perverted sensation than in the other cases. Sensation seemed to have returned somewhat, and it was interesting to speculate as to whether it would ever return completely, and, if so, by what route. Preservation of the sense of taste after division of the second and third divisions was to be noted. That the power of recognizing heat and cold existed in a region rendered devoid of ordinary

sensation by nerve section was of much interest, and recalled an observation made some time since that a conjunctiva rendered insensitive by the local application of cocaine still appreciated the difference between heat and cold.

When severing the third division of the nerve in the fourth case, Dr. Tiffany believed that he had isolated and recognized the motor branch before dividing it. Not having provided himself with a sufficiently long and fine electrode, he had not been able to prove the accuracy of his opinion by electric stimulation, and had therefore divided everything. By leaving the motor branch intact, the patient would be protected from having food collect in the cheek of the paralyzed side, and in future operations an effort should be made toward this end.

The Vaginal Route as compared with the Abdominal for the Removal of Pelvic Viscera.—

In a paper thus entitled Dr. GEORGE J. ENGELMANN, of St. Louis, called attention to the advantages offered by the vaginal route for many of the operations, and especially some of the more dangerous, now practiced by means of abdominal section for the removal of the uterus and appendages, and particularly in suppurative cases with multiple centers of suppuration. It was vaginal hysterectomy for malignant disease of the uterus which had first paved the way to the more extended use of the vaginal route for such operations. The author paid a fitting tribute to American surgery when he said that this, like others of the great operations of recent times, had emanated from a Southern surgeon. In New Orleans, in 1846, Dr. Dubourg had fully described this operation, and repeatedly practiced it with success since 1829, but it had been forgotten again until it was revived within the last decade, and vaginal hysterectomy for malignant disease of the uterus was now everywhere an accepted operation, which had been rendered especially safe and rapid by Péan's forcipressure method, and it was the French surgeon who had extended the field to the removal of other contents of the pelvis by the vaginal route, resorting to piecemeal removal (*morcellement*) for the extirpation of masses too large to be extracted in their entirety through the vaginal opening. The leaders in this new departure had been Péan and Sigond, of Paris, Doyen, of Reims, and Jacobs, of Brussels, and it was followed for the present by the French school only. In Germany and England these operations were practiced but little if at all, and in this country the vaginal route was limited to the removal of the uterus, with perhaps an operation for prolapse or inversion. In isolated cases the removal of prolapsed ovaries resting on the vagina, or of small and conveniently situated ovarian cysts through the vaginal opening, was now and then performed everywhere, but this was a very different matter. The surgeons who were leading in this field varied somewhat in their methods and in the extent to which they applied them, but the vaginal route now served them: 1. For hysterectomies for the removal of malignantly diseased uteri and moderately enlarged uteri, for hysterectomy by *morcellement*, and for uterine tumors which did not extend above the navel. 2. For the bilateral removal of appendages with diseased uteri. 3. For the treatment of pelvic suppuration of all kinds. Dr. Jacobs even preferred the vaginal method for certain cases in which the appendages of one side only were to be removed. Péan limited hysterectomy by *morcellement* to benign growths and to all cases of pelvic suppuration treated to-day by laparotomy, while Sigond still preferred laparotomy when an operation was indicated in unilateral cases, above all in unilateral salpingo-oophoritis when non-suppurative. The indication given by Terrier and indorsed by Jacobs for the resort to the vaginal route was, first, for cases in which suppurative pelvic peritonitis had returned if laparotomy had already been practiced; secondly, for suppurative pelvic peritonitis with fixation of the uterus and multiple pus sacs,

while laparotomy might be resorted to in enucleable non-suppurative salpingo-oophoritis.

The advantages of the vaginal route were the rarity, if not absence, of shock in cases in which we should have to treat it if the abdominal method was resorted to; the rapidity of the operation, by reason of the forcipressure method and the total absence of ligatures and sutures, the nearness of the parts to the finger, and in aggravated suppurative cases the guarding of the abdominal cavity from the pelvis proper, or the field of operation, by the adhesions and inflammatory products, which formed a perfect barrier. It seemed the natural route for reaching the parts below the pelvic brim. There was after the operation perfect drainage established by the forceps and the dressing *per vaginam*, so that there was no possible stagnation. Recovery appeared to be more rapid and more satisfactory than by the abdominal method. The forceps was removed in forty-eight hours, and the patient was sitting up on the fifth or sixth day, and moving about between the tenth and fourteenth, when cicatrization was completed.

Trephining as a Cure for Traumatic Epilepsy.—This was the subject of a paper read by Dr. JOHN T. CHAPMAN, of Bessemer, Ala. The author had operated on a boy who some years previously had received an injury of the head from a blow, fracturing the parietals. Three weeks after the injury he began to have epileptic convulsions. At the time Dr. Chapman saw the patient the convulsions had become more frequent and more severe. Two buttons of bone were removed at the seat of injury; there was considerable pressure from the depressed bone, and the membranes were hard and indurated. The indurations were cut out and the edges of dura brought together by continuous suture. The wound healed by first intention. For two months after the operation the patient continued to have convulsive seizures, but they gradually grew less until they ceased. The operation had been done four years and a half since. The patient was now eighteen years old, weighed a hundred and seventy pounds, and worked in a foundry. The author believed that the doctrine that depressed fractures of the skull without symptoms required no operative interference was in a measure at the bottom of many of the unfortunate sequelæ of head injuries.

The President's Annual Address was then delivered. The president said that six years before, a small band of earnest, brave, and determined Southern surgeons had assembled in the city of Birmingham, Ala., with Dr. Haggard as president, amid doubts, anxieties, and misgivings for the future, to found and organize an association that would meet the advanced requirements of the times, and rank in point of talent, efficiency, and high-toned character with the other great institutions of the kind in this and other countries. Notwithstanding the stupendous difficulties encountered, the vast labor expended, and the many obstacles in its path, the association stood to-day a monument of energy, enterprise, and indomitable will power.

Remarks on the Surgical Treatment of Epilepsy.—This was the title of a paper read by Dr. B. E. HADRA, of Galveston, Texas. He thought that modern researches promised to divest even the so-called genuine epilepsy of its mysterious functional character, and to make it consequently more accessible to surgical interference. Among the points he would mention as having to be cleared up was the deficiency in our knowledge of the great number of brain centers that must exist. As an instance he mentioned the unquestionable fact that very often the stomach or the intestines gave the initial symptoms, but because we did not yet know these centers, and because the signals were very abstruse, it might easily happen that another group of muscles, which had only secondarily become excited, was charged with giving the signal. The next point was to find

the real seat of the primary morbid changes in the brain, which was not necessarily the focus belonging to the initial signal. Topographical and electrical localization mapped out only the latter. The author insisted that the induced current used in a different way would be all we might desire for such a purpose. It must be applied over a large area of the exposed cortex until a spot was met from which not only a certain group of muscles could be made to contract, but a regular epileptic fit could be elicited. This spot must be the locality of the morbid substratum, whether it coincided with the physiological focus of the muscles giving the signal or not; consequently this spot must be removed.

The Management of Epicycstic Fistula.—This was the subject of a paper read by Dr. JOHN D. S. DAVIS, of Birmingham, Ala. He said the epicycstic surgical fistula was the title given to a suprapubic fistula opening into the bladder created by the surgeon for exploration, intravesical treatment, or drainage—a fistula which, acting as an artificial urethra, was capable of giving free access to the inside of the bladder for cystoscopic exploration, and of providing a ready, convenient, and comfortable means of emptying the bladder at will, and gave the surgeon a competent opening into the viscus for intravesical applications. It constituted an essential element in the speedy and complete evacuation of the contents of the bladder in all epicycstic operations, and imitated Nature in the restoration of the continuity of the urinary tract as the pathological changes within the bladder subsided.

Permanent after-drainage in all intravesical operations could not be necessary, but it was highly essential to secure good and sufficient drainage until the paracystic tissue was disengorged, the cystitis was relieved, and the urine had become normal and passed *per urethram* unobstructed. Until this end was attained, a complete artificial arrangement for the escape of the contents of the viscus must be made. In cases of prostatic hypertrophy or malignant growths, when removal of the obstruction was impossible or contra-indicated, the epicycstic surgical fistula was clearly indicated and essentially necessary.

A series of cases of **Tuberculosis of the Bladder** was reported by Dr. HUNTER MCGUIRE, of Richmond.

Personal Experience in the Operative Treatment of Stone in the Bladder.—This was the subject of a paper read by Dr. WILLIAM T. BRIGGS, of Nashville. The author said that when living in the midst of the stone region, and in a city whose celebrity as a surgical center had been long established, it had been his fortune to meet with an unusually large number of cases of vesical calculi. He had had two hundred and eighty-four cases of stone under observation during the past forty-two years. The Southern States had furnished the greater number of the cases, and a few had come from the Western States. Tennessee, Kentucky, and Alabama had supplied the largest number. Two hundred and seventy-two of the patients had been men, and twelve women. One hundred and fifty-three had been children or youths under twenty years of age, and one hundred and thirty-one adults varying in age from twenty-one to eight years.

In operations for stone he had not restricted himself to any single method. He had done all the operations, both cutting and crushing, and he considered it very fortunate that surgery had so many resources for the relief of this distressing and painful malady. The success of every method of operating largely depended on the preparatory treatment of the patient. The pre-eminent success of Dudley, Mott, and others had doubtless been due to the judicious treatment employed in the preparation of subjects for the operation, and the author was sure that his own success had been greatly enhanced by a strict observance of the preparatory treatment.

In conclusion, Dr. Briggs said his experience in the surgical treatment of stone in the bladder would sustain the following propositions: 1. No method of operation was adapted to all cases. 2. Thorough preparatory treatment was essential to success. 3. Litholapaxy was the operation when the patient was an adult with a capacious and tolerant urethra, with a bladder free from severe chronic inflammation, and with a small or medium-sized stone or, if large, of soft consistence. 4. The suprapubic was the best operation for large and hard calculi. 5. The medio-bilateral operation should be chosen in all other conditions, because it was the easiest, safest, and best.

Hypertrophy of the Omentum in Hernia, with a Specimen.—Dr. GEORGE A. BAXTER, of Chattanooga, read a paper with this title and presented a specimen (congenital) of about the size of a goose egg from a negro thirty-four years of age. It had been directly increased somewhat by his working in a rolling mill thirteen years ago, but had had a constant growth since that time until it reached half or two thirds of the way to the knees, and had become an unendurable nuisance. It was therefore removed.

The Treatment of Gunshot Wounds.—Dr. WILLIS F. WESTMORELAND, of Atlanta, read a paper thus entitled. The first of this class of injuries that he had been called upon to treat was shortly after he had graduated, and it had thoroughly convinced him of the fallacy of probing. He never used a probe in a gunshot wound except as it might become necessary in the progress of a formal antiseptic operation. The probing rarely did any good beyond satisfying a morbid curiosity. Even if the wound was not infected by the probe itself, it allowed the entrance of air. It destroyed Nature's occlusive blood clot and in this way prevented prompt union.

Wyeth's Bloodless Method in Amputation at the Hip.—

Dr. F. W. PARHAM, of New Orleans, prefaced his paper on this subject by reading some extracts from a paper by Dr. John A. Wyeth which had been read before the last meeting of the New York State Medical Association. He made use also of the statistics kindly furnished him by Dr. Wyeth. These statistics were as follows: Sarcoma, 17 cases, 2 deaths, 11-76 per cent.; inflammatory bone disease, 18 cases, 3 deaths, 16-6 per cent.; violence, 4 cases, 4 deaths, 100 per cent.; nerve injury, 1 case, no death. Total for disease, 36 cases, 5 deaths, 13-88 per cent.; for injury, 4 cases, 4 deaths, 100 per cent.; for both disease and injury, 40 cases, 9 deaths, or a total of 22-5 per cent. In this list there was one case now published for the first time. These statistics showed a mortality reduction for civil practice of at least one half. Ashburst's statistics gave 40-2 per cent. for disease and 82-4 per cent. for injury, or a total of 64-1 per cent. Leming gave for gunshot wounds 98 per cent., for disease 42 per cent.

Dr. Parham referred to the various methods proposed for controlling hemorrhage and spoke of the various modifications of the Wyeth method. He specially urged that the outer pin should be placed higher, so that the disarticulation might be done before the tube was removed. He favored Thomas's suggestion that in placing the pins the tube should be put around first at the proper place, and that then the pins should be put in at the lower border of the tube. He believed that the bone should be disarticulated entirely without sawing. In conclusion, the reader remarked, "I am inclined to agree with Murdoch that the method of Wyeth is the best yet devised."

Laparotomy in General Surgery.—A paper embodying a report of twenty cases was read by Dr. W. B. ROGERS, of Memphis.

Operative Procedures for Carcinomatous Tumors of the Breast.—Dr. J. McFADDEN GASTON, of Atlanta, Ga., read a paper thus entitled. He said that a point of great moment as

to the extent of operative procedure pertained to the leaving of any portion of the mammary gland when only partially implicated in the carcinomatous growth. The æsthetic element should never enter into the decision of such a vital question as the arrest of carcinoma, and whenever a breast was the seat of a malignant tumor, whether wholly or partially involved, there should be no hesitation about removing the entire glandular structure. If only a part of the mammary gland seemed to be involved and it was evident the knife could be carried outside the neoplasm into the apparently sound tissues of the breast, there was every reason to believe that if any portion of the gland was left it might become the seat of disease and that recurrence would most probably follow the operation. On the other hand, an entire ablation offered better prospects of success.

The relative advantages of the knife and cauteries in the management of carcinoma depended very much upon the progress of the disease. In the incipency of the local trouble there could be no doubt in regard to excision being preferable to cauterization, but after full development of a tumor with a tendency to degeneration and breaking down of its structure the resort to escharotics had its advantages in extending to the remote ramifications of the disease. It was a prevalent impression that certain caustic applications attacked diseased structures without affecting the sound tissues, and that the so-called roots of a cancer were thus destroyed. There seemed to be some just foundation for this belief in regard to applications of arsenic, but the destructive effect of caustic potash in the form of Vienna paste extended to every vital structure with which it came in contact, and the same held in reference to the plaster of sulphuric acid and charcoal as an escharotic.

Dr. Gaston said the treatment of carcinomatous tumors of the breast with caustics had been tested fully by Bougard, of Belgium. His paste contained chloride of zinc, arsenic, cinabar, and corrosive sublimate. Of one hundred and sixty cases, sixty-two, or nearly forty per cent., had been free from recurrence three years after treatment.

The Diagnosis of Some Abdominal Tumors supposed to be Ovarian.—This was the title of a paper by Dr. JAMES A. GOGGANS, of Alexander City, Ala. He said the first requisite of the abdominal or pelvic surgeon was to acquire the ability to make a diagnosis. Text-books led one to believe that this was quite an easy thing to do, but his experience had convinced him to the contrary. He then reported a few cases which had come under his observation which served to illustrate the fact that the diagnosis was often difficult, and in some cases quite impossible.

Does Gonorrhœa in the Female invariably prevent Conception?—Dr. JOHN T. WILSON, of Sherman, Texas, read a paper thus entitled. He said it had long been known that gonorrhœa in women was sometimes attended with complications that proved troublesome and of serious import. Authors had for many years been describing endometritis, metritis, and inflammations of the Fallopian tubes, ovaries, and peritonæum produced by an ascending specific elytritis, these structures being invaded by the poison slowly creeping up through the cervix, involving first the mucous membrane in its tract and extending by continuity of structure to the deeper tissues. The more serious results, however, had not been appreciated or so well understood until within recent years, when laparotomy had become so common an operation and the pathology of the more important sequelæ was studied from the specimens themselves. According to the experience of our best authorities, it was very difficult to distinguish positively between gonorrhœal and severe simple elytritis without a clear and authentic history, for both were attended with the same symp-

oms and with the property of infecting the male; so that it was not altogether an easy task to say when ovarian, tubal, and uterine troubles, even with the presence of the Neisser gonococcus, had a specific origin, especially as simple elytritis would sometimes produce them all. Dr. Wilson had observed quite a number of women who were the victims of gonorrhœal infection, many of them innocently, having contracted it from their husbands, and had believed the trouble to be an ordinary leucorrhœa. Many of those whose history he had been enabled to follow had afterward borne children, had remained for many years apparently healthy, and had given no evidence of the usual complications.

Dr. Wilson then reported cases illustrative of some of these conditions and results. That gonorrhœa did frequently prevent conception was probably well established; but he did not think it was by any means the universal rule—clinical illustrations were too many to the contrary. If Noeggerath's statements were literally true, sterile women and fruitless marriages would be far more common and the increase in the race would be greatly lessened, for there was a surprisingly large percentage of men, judging from his experience, who, if they confessed the truth, had suffered at some time in their lives with gonorrhœa.

Some Remarks on the Practical Treatment of Hepatic Abscess.—Dr. JAMES E. THOMPSON, of Galveston, Tex., in a paper with this title, confined himself to a few practical remarks on the diagnosis and treatment of hepatic abscess, and reported two interesting cases. He mentioned a few points on the treatment of the cavity after the contents had been successfully removed. It was often exceedingly difficult to obtain free drainage even when large tubes were employed. In some cases even swabbing the walls of the cavity was ineffectual, and these cases were practically hopeless, owing, perhaps, to inherent tissue weakness. The author had tried curetting in one of his cases, and, although he removed, as he thought, all necrotic tissue, still in a few days the cavity was as bad as before. Continuous irrigation often afforded a means of efficient removal, but the tubes had an aggravating habit of becoming blocked and requiring frequent changing and cleaning. Irrigation with a solution of sulphate of quinine—1 to 1,000—had in one of his cases been remarkably successful, and, although the improvement might have been a coincidence and not an example of *post hoc ergo propter hoc*, he thought that in cases of amœbic dysentery, at least, it deserved a fair trial.

Officers for the Ensuing Year were elected as follows: President, Dr. Cornelius Kollock, of Cheraw, S. C.; vice-presidents, Dr. A. B. Miles, of New Orleans, and Dr. J. B. S. Holmes, of Rome, Ga.; secretary, Dr. W. E. B. Davis, of Birmingham, Ala.; treasurer, Dr. H. P. Cochran, of Franklin, Tenn. The association adjourned to meet in Charleston, S. C., on the third Tuesday in November, 1894.

Book Notices.

The Students' Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation, and Full Explanation of Medical Terms, together with much Collateral Descriptive Matter, Numerous Tables, etc. By ALEXANDER DUANE, M. D., Assistant Surgeon to the New York Ophthalmic and Aural Institute, etc. Philadelphia: Lea Brothers & Co., 1893. Pp. viii+650. [Price, \$4.25.]

This medical dictionary is, as the title indicates, primarily intended for students.

Obsolete and rare terms have been omitted; only words in actual use are to be found in it, and they are briefly defined. The space thus gained has been devoted to explanatory matter, such as the causes, symptoms, and treatment of diseases, an outline of the structure and functions of the more important organs, and an account of the action and therapeutic uses of each drug and of all the preparations of it official in the latest editions of the pharmacopœias of the United States, Great Britain, and Germany.

The subjects of *Bacteria* and *Fungi* are treated in a clear and succinct way by means of a tabular view giving their names, origin, and morphological characters, the temperature at which they flourish, and their properties.

This table is followed by a list of the diseases caused by *Bacteria*. A tabular treatment of arteries, muscles, nerves, canals, and certain other subjects has also been adopted.

The inclusion of this encyclopædic information constitutes a useful, though not, as the author says in his preface, a characteristic feature of the work.

Strict alphabetical order has been practically followed in the major headings, but alphabetical has been made subservient to logical order in the subheadings.

While one appreciates the author's consideration for persons unfamiliar with Greek, as shown in his printing the original Greek words in Italics, it is an open question whether the memory of persons unacquainted with Greek may be sufficiently impressed by words in an unknown language to compensate for this sacrifice of literary *tenue*.

Discretion has been shown in deciding disputed points of spelling. The best usage, regardless of analogy, has been adopted as the standard. In cases of variation in good usage and conflict of authorities, that orthography has been adopted that seemed most in harmony with the derivation of the word and with analogy. *Anthelminthic* has been preferred to *anthelmintic*, and *chorioid* to *choroid*, but *thyreoid* has not been substituted for *thyroid*.

The scheme of pronunciation and accentuation seems to us unsatisfactory. For instance, why should the author seek to differentiate the sounds of a in *at* and a in *man*, representing the sound of the latter by æ?

We find *accoucheur*, although considered as a French word not anglicized, accented ak'oo-shur', yet a man of the author's attainments must surely know that the beloved ideal of France, equality, manifests itself even in the laws of her language, and that every word constitutes a little democracy in which each syllable possesses equal rights.

BOOKS, ETC., RECEIVED.

A Text-book of Physiological Chemistry. By Olof Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Second Swedish Edition and from the Author's enlarged and revised German Edition. By John A. Mandel, Assistant to the Chair of Chemistry, etc., in the Bellevue Hospital Medical College and in the College of the City of New York. New York: John Wiley & Sons, 1893. Pp. x-511. [Price, \$4.]

Manual of Bacteriology for Practitioners and Students, with Especial Reference to Practical Methods. By Dr. S. L. Schenk, Professor Extraordinary in the University of Vienna Translated from the German (by the Author's permission) with an Appendix by W. R. Dawson, B. A., M. D., University of Dublin, etc. With One Hundred Illustrations, partly colored. London and New York: Longmans, Green, & Co., 1893. Pp. xiv-310. [Price, \$3.]

Information for Nurses in Home and Hospital. By Martin W. Curran, Graduate of the Mills Training School, Bellevue

Hospital, New York City. Illustrated. New York: J. H. Vall & Co. Pp. xvi-333. [Price, \$1.50.]

An Outline of the Embryology of the Eye. With Illustrations from Original Pen Drawings by the Author. By Ward A. Holden, A. M., M. D., Assistant Surgeon, New York Ophthalmic and Aural Institute, and Clinical Assistant, Vanderbilt Clinic. New York and London: G. P. Putnam's Sons, 1893. Pp. 69. [Price, 75 cents.]

Asiatic Cholera: its History, Pathology, and Modern Treatment. By A. J. Wall, M. D., Fellow of the Royal College of Surgeons of England, and of the Medical Staff of H. M. Indian Army (Retired List). London: H. K. Lewis, 1893. Pp. vi-194.

The Cholera Epidemic of 1892 in the Russian Empire. With Notes upon Treatment and Methods of Disinfection in Cholera, and a Short Account of the Conference on Cholera held in St. Petersburg in December, 1892. By Frank Clemow, M. D. Edinburgh, Member of the Epidemiological Society of London, etc. London and New York: Longmans, Green, & Co., 1893. Pp. xii-123. [Price, \$1.75.]

A Theory of Development and Heredity. By Henry B. Orr, Ph. D., Professor at the Tulane University of Louisiana. New York and London: Macmillan & Co., 1893. Pp. ix-255. [Price, \$1.50.]

The Essentials of Chemical Physiology, for the Use of Students. By W. D. Halliburton, M. D., F. R. S., Fellow of the Royal College of Physicians, and Professor of Physiology in King's College, London, etc. London and New York: Longmans, Green, & Co., 1893. Pp. xi-166. [Price, \$1.50.]

Outlines of Obstetrics. A Syllabus of Lectures delivered at the Long Island College Hospital. By Charles Jewett, A. M., M. D., Professor of Obstetrics and Pædiatrics in the College and Obstetrician to the Hospital. Edited by Harold F. Jewett, M. D. Philadelphia: W. B. Saunders, 1894. Pp. 264.

Ophthalmic Nursing. By Sydney Stephenson, M. B., F. R. C. S. Edinburgh. With Sixty-one Illustrations. London: The Scientific Press (Limited), 1894. Pp. xii-188. [Price, 3s. 6d.]

Études anatomo-pathologiques. L'Inflammation. Par Maurice Letulle, Professeur agrégé à la Faculté de médecine de Paris et médecin de l'Hôpital Saint-Antoine. Paris: Georges Masson, 1893. Pp. xi-531.

Results of Aseptic Cæliotomy. By William H. Wathen, A. M., M. D., of Louisville, Ky. [Reprinted from the *American Journal of Obstetrics*.]

The Prevention and Management of Pelvic Inflammation in Puerperal Women. By Horace Tracy Hanks, M. D., of New York. [Reprinted from the *American Medico-surgical Bulletin*.]

Secondary Hæmorrhage after Ovariectomy. Can we Prevent it? By Horace Tracy Hanks, M. D., of New York. [Reprinted from the *Transactions of the American Gynecological Society*.]

Counter-drainage after Cæliotomy. By Horace Tracy Hanks, M. D., of New York. [Reprinted from the *Post graduate*.]

Removal of the Ossicles. By J. E. Sheppard, M. D., of Brooklyn, N. Y. [Reprinted from the *Annals of Ophthalmology and Otolaryngology*.]

Present Views on Intubation of the Larynx. By S. W. Kelley, M. D., of Cleveland, Ohio. [Reprinted from the *Cleveland Medical Gazette*.]

Report on Nasal Surgery. With Illustrated Cases. By M. F. Coomes, A. M., M. D., of Louisville, Ky. [Reprinted from the *American Practitioner and News*.]

Brain Preservation. With a Résumé of Some Old and New Methods. By Pierre Augustine Fish, B. S. [Reprinted from the *Wilder Quarter-Century Book*.]

The Use and Place of Caustics in the Treatment of Cancer. By Daniel Lewis, M. D., of New York. [Reprinted from the *Annals of Surgery*.]

Hydrocystoma. By A. R. Robinson, M. B., L. R. C. P. and S. (Edin.). New York. [Reprinted from the *Journal of Cutaneous and Genito-urinary Diseases*.]

A Case of Distoma Hiematobium. By J. L. Hillmantel, M. D., of Chicago. Read before the Chicago Medical Society, September 10, 1893. [Reprinted from the *Chicago Medical Recorder*.]

The Lake and Brook Lampreys of New York, especially those of Cayuga and Seneca Lakes. By Simon Henry Gage, B. S., of Ithaca. [Reprinted from the *Wilder Quarter-Century Book*.]

The Brain of *Diemyctylus Viridescens*, from Larval to Adult Life; and Comparisons with the Brain of *Amia* and of *Petromyzon*. By Susanna Phelps Gage, Ph. B. [Reprinted from the *Wilder Quarter-Century Book*.]

L'ictiolo nella cura della blenorragia. Per il Dott. Pio Colombini. [Estratto dal *Commentario clinico delle malattie cutanee e genito-urinarie*.]

L'ictiolo nella terapia delle forme cutanee e venereo-sifilitiche. Per il Dott. Remo Segre. [Estratto dagli *Atti dell'Associazione Medica Lombarda*.]

Aus dem hygienischen Institut der Universität Greitswald. Ueber der antiseptische Kraft des Ichthyols. Von Dr. Rudolph Abel. [Abdruck aus dem *Centralblatt für Bakteriologie und Parasitenkunde*.]

Ueber Ichthyol-suppositorien bei der Behandlung der Prostatitis. Von Dr. A. Freudenberg in Berlin. [Sonder-Abdruck aus dem *Centralblatt für klinische Medizin*.]

Ninth Annual Report of the Providence Lying-in Hospital, 1893:

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Ninety-fourth Annual Session. Held at Baltimore, Md., April, 1892. Semi-annual Session, held at Rockville, Md., November, 1891.

A System of Genito-urinary Diseases, Syphilology, and Dermatology. By Various Authors. Edited by Prince A. Morrow, A. M., M. D., Clinical Professor of Genito-urinary Diseases, formerly Lecturer on Dermatology in the University of the City of New York, etc. With Illustrations. In Three Volumes. Vol. II, Syphilology. New York: D. Appleton & Co., 1893. Pp. xvii-917.

The Students' Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation, and Full Explanation of Medical Terms, together with much Collateral Descriptive Matter, Numerous Tables, etc. By Alexander Duane, M. D., Assistant Surgeon to the New York Ophthalmic and Aural Institute, etc. Philadelphia: Lea Brothers & Co., 1893. Pp. viii-650. [Price, \$4.25.]

Healthy Hospitals. Observations on Some Points connected with Hospital Construction. By Sir Douglas Galton, late Royal Engineers, K. C. B., Hon. D. C. L., LL. D., F. R. S., etc. With Illustrations. London: H. K. Lewis, 1893. Pp. xi-287.

A Text-book of Physiology. By M. Foster, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge, etc. With Illustrations. Sixth Edition. Part I, comprising Book I. Blood. The Tissues of Movement. The Vascular Mechanism. New York and London: Macmillan & Co., 1893. [Price, \$2.60.]

The Narrative of a Busy Life. An Autobiography. By Arthur Hill Hassall, M. D. Lond., Member of the Royal College

of Physicians of London, etc. London: Longmans, Green, & Co., 1893. Pp. iii-82.

A Modification in the Technique of Operations for the Repair of Complete Perineal Lacerations. By William B. Van Lennep, A. M., M. D., Philadelphia. [Reprinted from the *Hahnemannian Monthly*.]

AN ASEPTIC NASAL SPECULUM.

By EDWARD A. SCOTT, M. D.

In anterior rhinoscopy it is very desirable that we should have instruments that can be cleaned quickly and thoroughly, and that all screws and inaccessible parts be tabooed wherever possible, owing to the fact that in this region we have to deal with syphilitic and diphtheritic lesions, the transmissibility of which is apparent, and therefore the necessity of instruments of the cleanest kind, and if possible without angles or places liable to retain anything, no matter what its nature.

The accompanying cut shows a nasal speculum that meets these requirements in every sense, as there is no place that can in any way afford shelter to anything of any kind.

The disadjustment of the instrument consists in simply pressing and then turning the retaining spring, after which the two handles are easily unlocked by approximation; and for readjustment the reverse process only is necessary.

Miscellany.

Long-continued Fevers in Louisiana.—At a recent meeting of the Orleans Parish, Louisiana, Medical Society, Dr. Martin read a paper on this subject. He desired to prompt a discussion on a subject which, though not entirely new to the society, was, he believed, most deserving of consideration. He had had to cope recently with a type of fever foreign to any represented in our text-books. From older practitioners he learned that these slow fevers of Louisiana, which resisted all

forms of treatment and which were sometimes more aggravated than benefited by quinine, were of recent origin in the State. With the many forms of malarial fever we were thoroughly conversant, though it was his belief that the word "malaria" was too often used to supply a want in the absence of a diagnosis. In his own brief experience he had known a case of abscess of the liver to be diagnosed and treated for six weeks as one of malarial remittent fever. Also a case of pelvic cellulitis, notwithstanding the local pain, had been diagnosed as malarial. In such cases, however, a correct solution of the case was generally arrived at before any serious trouble arose. But an error of this kind in the diagnosis of typhoid fever would, at least in his hands, have proved fatal. We should bear in mind that, notwithstanding the teachings of our professors, typhoid fever did exist in this community, and to such an extent that it was time for us to eradicate from our minds old prejudices so thoroughly instilled in past years, for there could no longer be a doubt of its existence, and we should be prepared to meet it at any time.

Was it not possible that many of the so-called cases of typho-malarial fever were modified forms of typhoid? Might not climatic influences have moderated the disease, for it was certain that few, if any, typical cases had ever originated in the city? Malarial and typhoid fevers were distant forms and easily diagnosed, making the treatment clear. Another form of continued fever existed, so different in its origin, in its symptoms, and in its cause from either of these two forms, that he had deemed it his duty to introduce the subject and to ask the members to give the matter their time and consideration. This fever, he had observed, was usually ushered in without any premonitory symptoms. The patient usually complained of feeling dull; the tongue might or might not be coated; the bowels were costive, and loss of appetite ensued; sometimes there were nausea and slight elevation of temperature, but seldom any functional disturbance. The temperature would vary from 99° to 103°, and the fever would continue from three to nine weeks. Patients were not greatly exhausted by the fever and were sometimes able to keep about their work. One patient whom he had had under treatment, a robust person, had never been compelled to lie down during the day, but had spent the time in a large armchair. The fever had lasted ten weeks. In this case he believed its long continuance had been partly due to malnutrition. Nausea had complicated the case, and the question of treatment had become a serious problem until he had had recourse to raw eggs and sherry. This had constituted the nourishment during the day, the patient having taken as many as half a dozen eggs in twelve hours. At night the author had given mullied milk, which had proved a soothing and nutritious beverage. Through the entire course of the illness he had been at a loss to detect any one symptom sufficiently marked to point to a diagnosis. If malarial, it had not been typical in appearance.

For some time he had been inclined to believe it septic, but a most careful examination of every organ in the body, repeated several times, had failed to substantiate this belief. As regarded treatment, he had employed every form known to science without success. Quinine was inert, and antipyretics gave but temporary relief. The case would run its course and must be treated symptomatically. His method of managing these cases had always been purely symptomatic, not expectant—to relieve pain, regulate the bowels, reduce the temperature, and tempt the appetite.

If there were any present whose misfortune it had been to meet with such cases, he trusted the results had been more gratifying, and that they had settled upon a diagnosis and a formulated plan of treatment.

Original Communications.

A STUDY OF

THE LEUCOCYTOSIS OF LOBAR PNEUMONIA.

By JAMES EWING, M.D.,

ASSISTANT IN NORMAL HISTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS,
COLUMBIA COLLEGE; ASSISTANT PATHOLOGIST TO ROOSEVELT HOSPITAL.

DURING the past few years the subject of leucocytosis has been rapidly growing in interest. It has long been known that in certain conditions, both physiological and pathological, the number of leucocytes in the blood rises considerably above the normal limit—eight thousand to the cubic millimetre. Only recently, however, has this phenomenon received any systematic study, and its practical importance been recognized.

At present the extent of our clinical knowledge may be briefly summarized as follows:

During digestion and in pregnancy there is a moderate physiological increase in the number of leucocytes in the blood.

In many pathological conditions, either cachectic or febrile, a constant and considerable leucocytosis has been demonstrated. The principal cachectic conditions producing leucocytosis are three in number: 1. The acute anæmia following hæmorrhage. 2. The chronic anæmia of diseases of the blood and of malignant neoplasms. 3. The condition of the blood before death, giving an "ante-mortem" leucocytosis.

Finally, there is the leucocytosis of inflammatory conditions, which is a regular accompaniment of many febrile diseases. Of these may be mentioned lobar pneumonia, inflammations of serous membranes, meningitis, septicæmia, acute articular rheumatism, scarlatina, diphtheria. Measles, typhoid fever, and pulmonary tuberculosis have been shown to be important exceptions in this class. In typhoid fever, the number of leucocytes is regularly subnormal, while in phthisis it is usually absent or inconspicuous.

The leucocytosis of lobar pneumonia has received more attention than that of any other febrile condition. Its course during the disease has been carefully followed in sixteen cases recently reported by Laehr. Its relation has been noted to the height of the fever, to the extent of the pulmonary lesion, to the amount of poison generated by the disease, and to the reaction of the system. Some have claimed that the degree of leucocytosis follows exactly the extent of the local lesion; others, that it is regulated by the amount of poison generated and by the character of the systemic reaction excited by the disease. Its relation, also, to prognosis has been considered and attempts made to base a favorable prognosis on a high degree of leucocytosis. Von Jaksch* has observed that cases of lobar pneumonia unaccompanied by leucocytosis are of unfavorable prognosis. Laehr† reports a case in

which a relapse was heralded by a recurrence of leucocytosis after its disappearance with the crisis. Laehr and Rieder* believe that the examination of the blood is of great value in the diagnosis between lobar pneumonia and typhoid fever. The number of leucocytes in the blood in phthisis has been found so variable that no definite rules have been established as to the use of the blood count in distinguishing this disease from pneumonia.

In order to test the truth of the statement that a large increase in the number of leucocytes in the blood offers a favorable prognosis in lobar pneumonia, the writer examined the blood in a hundred and one cases of this disease occurring in Roosevelt Hospital during the first five months of the year 1893. In the belief that the determination of leucocytosis could hardly become a matter of general utility if a lengthy series of examinations were required in each case, the observations were limited to a single examination made during the height of the disease, which is a practical procedure. Laehr's investigations, in which the entire course of the leucocytosis was followed, show that a single examination made at such a time gives an accurate indication of the leucocytosis in a case of pneumonia.

Technique.—The instrument usually employed in counting white blood cells is known as the Thoma-Zeiss leucocytometer. In the method recommended for this instrument the blood is treated with a three-tenths-per-cent. aqueous solution of acetic acid, which destroys the red blood cells, leaving only the white. In using this method several disadvantages became apparent. The quantity of blood required is inconveniently large. Acetic acid obscures the outlines of the leucocytes and it is often difficult to distinguish them from débris left by the red blood cells. The leucocytes become very cohesive and appear in the counting chamber in considerable masses, in spite of persistent efforts to secure the even distribution necessary for an accurate count. This method was therefore discarded and the ordinary instrument for counting red blood cells (the Thoma Zeiss) was used in all the cases.

The examination of the blood was made regularly between the hours of 9 and 12 P. M. The blood was drawn from the finger tip by a deep fine puncture, which usually causes a copious flow. It was thoroughly mixed in the pipette with a three-per-cent. salt solution colored deeply by gentian violet (about one per cent. of a saturated alcoholic solution). The drop received into the counting chamber was rejected unless it showed an even distribution of red cells. The first drop, after the leucocytes had been estimated, was replaced always by a second, and the second often by a third, and the average of the two or three counts was finally accepted.

The blood was examined in this way in about a hundred and fifteen cases of febrile disorder. They were principally cases of lobar pneumonia; but this number includes several cases of typhoid fever, typhus fever, acute

* Rieder. *Beiträge zur Kenntniss der Leucocytose*.

phthisis, empyema, and one case of actinomycosis of the lung. Several cases in which lobar pneumonia was wrongly suspected to exist and no leucocytosis found, and some

cases of chronic phthisis in which the usual variable result was obtained, are not reported.

The results are presented in the following tables:

Lobar Pneumonia.

Relation of Leucocytosis in Pneumonia to the Extent of the Pulmonary Lesion.—Limbeck, Pick, and others call attention to the fact that the degree of leucocytosis bears a very constant relation to the extent of the local lesion, and it is both asserted and denied that the extent of the lesion determines the grade of leucocytosis. An examination of the cases under discussion seems in general to show that the extent of the lesion influences considerably the number of leucocytes in the blood. In sixty-three cases in which one lobe was involved the average number of leucocytes was 20,000.

In twenty-four cases, involving two lobes, the average was 22,700. In twelve cases, involving three lobes, the average rose to 25,000.

In one case in which four lobes were affected the number was 27,000; and in Case 48, in which all the lobes were successively attacked, the number of leucocytes reached 32,000.

In the entire series, therefore, the number of leucocytes increases regularly with the number of lobes affected. On the other hand, the seven highest numbers observed accom-

panied the involvement of a single lobe. Hence the above assertion, while true of a series of cases, is an unsafe rule to apply to individuals. Further, in ten cases in which the lesion extended to the opposite pleura, the pericardium, or the peritonæum, the average degree of leucocytosis was relatively low (17,000).

Relation of Leucocytosis in Pneumonia to the Amount of Poison generated and to the Systemic Reaction.—That the prognosis of pneumonia depends upon the amount of poison generated and the vigor of the systemic reaction more than upon the extent of lung involved is a fundamental clinical rule. That the degree of leucocytosis in pneumonia also depends upon these two factors more than upon the extent of the lesion can be demonstrated, it is believed, from the foregoing cases.

Where the character of the infection was very mild the number of leucocytes was often correspondingly low, but since thirty-five per cent. of the fatal cases showed very slight leucocytosis, the amount of poison generated can hardly be considered a regular factor in determining the degree of leucocytosis.

In order to draw some conclusion about the relation of leucocytosis to systemic reaction, the cases were carefully divided, according to their clinical aspect, into three groups. The reaction of the system was judged as *vigorous* when the rectal temperature reached 105° or higher; when the pulse, while tumultuous, retained its force until the anatomical lesion was well advanced; when the general condition at the height of the disease was markedly sthenic; and when a fatal issue seemed not to be inevitable, but to result either from some complication or after a doubtful course.

The systemic reaction was considered *moderate* when the temperature was between 104° and 105°, while the other symptoms were less severe.

In other cases the reaction of the system was regarded as *slight*, with a temperature never reaching 104° and with moderate prostration. The reaction was regarded as slight or deficient also when the pulse began to fail very early; when the disease throughout was "badly borne," pursuing an asthenic, often rapidly fatal course.

In forty-seven cases, marked by a severe and powerful systemic reaction, the average number of leucocytes was 31,000. In twenty-seven moderate cases the average was 20,000. In twenty-seven cases, characterized by slight and deficient systemic reaction, the number of leucocytes averaged 9,000. Of eleven asthenic cases, placed with the last division, there was in six a decrease in the number of leucocytes.

The Diagnostic Value of Leucocytosis: Pneumonia vs. Typhoid Fever.—While it has been known for some years that there is no leucocytosis in typhoid fever, it is only within the past two years that our knowledge of the leucocytosis of lobar pneumonia has warranted any positive statement as to its value in the diagnosis of the latter disease. That the examination of the blood may be decisive evidence in distinguishing obscure forms of pneumonia from typhoid fever, the following cases may show. On account of the uncertain estimate then placed on such evidence, the blood count did not influence the diagnosis in any of the cases.

Eustace (100): Gradual onset with indefinite chill, dry cough, general pains, no dyspnea. Examination of lungs showed mild bronchitis. Abdominal symptoms prominent. Regarded as typhoid fever and persistently bled. Leucocytes, 34,000. Physical signs of pneumonia of right lower lobe began to appear on the tenth day—the day of defervescence by crisis.

Barry (110): Chill, cough, dyspnea, general chest pains. At bases of both chests, dullness, high-pitched breathing, a few moist râles. Pronounced a case of pneumonia. Leucocytes, 5,000. Two days later the lungs had cleared and typhoid symptoms were apparent. Relapse on the twenty-ninth day. Perforation on the thirty-seventh day. Pneumonia of right lower lobe on the fortieth day (90). Leucocytes, 5,000. Death on the forty-third day. This is one of the cases in which lobar pneumonia was unaccompanied by leucocytosis. It was also an excellent illustration of entire failure of systemic reaction, the pneumonia being masked by abdominal symptoms and only discovered by the routine examination of the chest.

Pearson (109): Chills, general chest pains, dry cough, no abdominal symptoms. General bronchitis, with diminished breathing at base of left chest. Regarded as pneumonia. Leucocytes, 6,000. Four days later the lungs had cleared, abdominal symptoms supervened, and the temperature ran a typical typhoid course.

Gavin (108): Chill, cough, subjective dyspnea. Few moist râles, possibly slight dullness, high-pitched voice and breathing at right apex. No abdominal symptoms. Regarded as pneumonia, but careful daily examination failed to locate it. Leucocytes, 8,000. Five days later, rose spots, diarrhoea, and further typical typhoid course.

Pneumonia vs. Typhus Fever.—The writer has been unable to find reported any examinations of the blood in typhus fever. Four such cases were encountered during the winter, and in none was there found any increase in the number of leucocytes. It is believed, therefore, that the examination of the blood is probably of equal value in the more difficult diagnosis between lobar pneumonia and typhus fever.

Byrnes (111): Chill, slight stitch in right axilla (?), febrile dyspnea, muco-purulent sputum. Slight dullness, diminished breathing, a few moist râles at bases of both chests, more marked at right. Regarded as certainly pneumonia. Leucocytes, 5,000. Physical signs were found not to advance satisfactorily after very careful examination twice daily, and on fourth day after admission typhus eruption appeared.

Black (112): Chill, stitch in side, febrile dyspnea. Slight dullness, diminished breathing, and moist râles at bases of both chests, especially the left. Regarded as pneumonia. Leucocytes, 8,000. Three days later bronchitis had cleared up and typhus eruption appeared.

McCord (10): Sent to hospital as a suspicious case of typhus fever. Three days before had had slight chill; no chest pains, no expectoration, no dyspnea. Pulmonary signs negative. Typhus and pneumonia were regarded as possibilities. Leucocytes, 27,000. No definite physical signs of pneumonia developed till after eight days of remittent pyrexia, when the case defervescenced by rapid lysis.

In two other cases of typhus fever (113, 114) no leucocytosis was found.

Pneumonia vs. Tuberculosis.—As has been said above, the number of leucocytes in the blood in pulmonary tuberculosis has been found so variable that no definite opinion has been reached as to the value of the blood count in distinguishing between lobar pneumonia and phthisis. Leucocytosis, however, has been shown to occur only in a minority of the cases of tubercular inflammation of the lung, and in these the number of leucocytes seldom reaches 15,000. Possibly the explanation of this occasional leucocytosis may be found in the first three cases next cited, which, at the time of the examination, were acute processes without suppurating cavities. In the writer's observation, while moderate leucocytosis has been found in chronic phthisis with suppurating cavities, yet in those cases of acute phthisis which clinically resemble lobar pneumonia the white blood cells have shown only the very slightest increase. It is possible also that the leucocytosis reported in some cases of phthisis may be due to chronic anemia, to a circumscribed pleurisy, or to a moderate lobar pneumonia, which frequently complicate the disease (as was shown by autopsy in Case 91).

The absence of leucocytosis may therefore be considered as valuable evidence in a decision between acute phthisis and all forms of lobar pneumonia, except the very mild and the severe asthenic cases. It was found to be so in the following instances:

Andrews (102): Professed to have been sick a week with chill, sudden pain in left side, cough, muco-purulent sputum, in which no tubercle bacilli were found. Tempera-

ture, 106°. Consolidation of left upper lobe. Regarded as certainly pneumonia. Leucocytes, 2,000. Lesion rapidly extended. Death in fifth week. Autopsy.

Dessar (103): Ill fourteen days, with usual history and signs of pneumonia of left lower lobe. Fairly typical rusty sputum in which no tubercle bacilli were found. Leucocytes, 10,000. Death on the twenty-seventh day. Acute phthisis, cavity in lower lobe, previously supposed to be gangrene, from fetid odor and apparent absence of bacilli.

Gram (105): A patient suffering from chronic Bright's disease and "bronchitis." Fever suddenly rose, cough became worse, with dyspnoea, stitch in left side. Signs of slight consolidation now found in front of the left upper lobe. Regarded as pneumonia. Leucocytes, 9,000. After ten days tubercle bacilli were finally found in the sputum.

Stark (104): Acute illness of few days' standing, with usual history of a moderately severe pneumonia of right upper lobe. Leucocytes, 12,000. Bacilli afterward found in the sputum.

Keen (95): Acute illness of ten days' duration. Previous history favored tuberculosis. General bronchitis; consolidation of most of right lung. Treated as phthisis. Leucocytes, 26,000. Repeated examination failed to find tubercle bacilli in the sputum, and recovery followed after tardy resolution.

Obscure Forms of Pneumonia.—The examination of the blood gave correct evidence in cases of obscure pneumonia when physical signs and other symptoms were indefinite.

Glavin (48): Suffering from chronic nephritis. Had fever, cough, muco-purulent sputum. Some indefinite signs over angle of left scapula raised a suspicion of pneumonia. These signs cleared up in a few days, and the idea of pneumonia was abandoned. The patient died in uræmia, and remains of pneumonia were found in the above location. Leucocytes, 19,000.

Ginty (80): A case of nephritis. One morning awoke with severe chill and pain in right axilla; temperature, 104°. Pulmonary signs insufficient for diagnosis. Leucocytes, 24,500. Disappearance of urinary chlorides. Temperature fell by crisis on the third day.

Pneumonia vs. Empyema and Actinomycosis of the Lung.—In two fatal cases of empyema and in one case of actinomycosis of the lung the leucocytes were considerably increased, and the examination of the blood was of no value in distinguishing the diseases from lobar pneumonia.

The Prognostic Value of Leucocytosis in Pneumonia.—Of one hundred and one cases of pneumonia, thirty seven were fatal. In the fatal cases the average number of leucocytes found was nineteen thousand five hundred; or from these thirty-seven, selecting thirteen cases occurring in fairly robust adults, the average may be brought as low as seventeen thousand. In sixty-four recoveries the average was twenty-four thousand one hundred. Evidently the difference between the average leucocytosis of a favorable and that of a fatal case is too slight to warrant strict confidence in its prognostic value. Not only are the averages close, but many of the fatal cases showed a very marked leucocytosis. It may be said, therefore, that a considerable leucocytosis

is no indication that the case will pursue a favorable course. Very accurate predictions, however, may be made from the examination of the blood when the relative value of such evidence is carefully estimated; for, of the fatal cases, above mentioned, attended with marked leucocytosis, thirteen may be explained by serious complications, such as nephritis, alcoholism, pericarditis, endocarditis, and old age. In fact, in only three of the fatal cases did a marked leucocytosis, when taken in apparently proper connection with other features of the case, point to a wrong conclusion. In several instances where recovery followed, a high leucocytosis was found at a time when the condition was considered hopeless.

An examination of the deaths will show that in severe forms of lobar pneumonia a slight leucocytosis is a very unfavorable sign. In six fatal cases the number of leucocytes was subnormal. In eleven fatal cases the average number was nine thousand. Not one case recovered in which the disease was of even moderate severity when the number of leucocytes fell below fourteen thousand. In several instances, again, a slight leucocytosis seemed at the time the only unfavorable prognostic sign in cases ending fatally.

Summary.—In most cases of lobar pneumonia there is a marked leucocytosis.

The leucocytosis of lobar pneumonia may be absent or inconsiderable—(a) in very mild cases; (b) in very severe cases in which the reaction of the system is slight.

The degree of leucocytosis in pneumonia is proportional, on the average, to the extent of the local lesion, but it follows much more exactly the grade of systemic reaction to the poison generated.

In cases of acute tubercular inflammation of the lung, clinically resembling lobar pneumonia, there was no leucocytosis.

In pulmonary phthisis complicated by suppurating cavities, exudative pneumonia, pleurisy, or chronic anæmia, there was usually a moderate leucocytosis.

In typhoid and typhus fevers there was no leucocytosis.

In empyema and actinomycosis of the lung there was considerable leucocytosis.

In obscure forms of lobar pneumonia, in which ordinary physical signs and rational symptoms are insufficient for diagnosis, the examination of the blood may give useful evidence.

Well-marked leucocytosis is a valuable aid in the differential diagnosis between lobar pneumonia and typhoid or typhus fevers.

In acute apical lesions the absence of leucocytosis is decisive evidence in favor of tuberculosis, except when dealing with a lobar pneumonia which is very mild, or whose course is asthenic.

The examination of the blood is of no value in the diagnosis between lobar pneumonia and empyema or actinomycosis of the lung.

Well-marked leucocytosis in lobar pneumonia, while in itself a favorable sign, does not assure that the disease will pursue a favorable course, but indicates usually a severe infection.

¹ A moderately low degree of leucocytosis in severe cases of lobar pneumonia is an extremely unfavorable sign.

In severe cases of lobar pneumonia absence of leucocytosis indicates, with rare exceptions, that the disease will prove fatal.

Most cases of lobar pneumonia in which the lesion extends to the pericardium and peritonæum are attended with slight leucocytosis.

RECENT STUDIES IN NAUPATHIA, OR SEASICKNESS.

SYMPTOMATOLOGY, DIAGNOSIS, PATHOGENESIS,
AND TREATMENT BY A NEW AND EFFICACIOUS METHOD.

By WINSLOW WARNER SKINNER, M. D. (PAR.),
FORMERLY SHIP'S SURGEON ON SEVERAL TRANSATLANTIC LINES, ETC.

(Continued from page 695.)

IV. *Ætiology and Pathogenesis.*—A. *Part based upon Observation and Experience.*—Let us briefly examine the few remote predisposing causes of naupathia. In the first place, it is not at all necessary to travel upon water to be seasick, or at least to exhibit the symptom group called seasickness when encountered on water. There are persons in whom merely the sight of a boat tossed by the waves suffices to render them seasick even while they themselves are standing on dry land. Others are sick on the railway train, in a carriage, even on horseback. The common swing and the merry-go-round possess the well-known property of producing nausea and vomiting in many persons who try these forms of amusement. A ride on a camel or a dromedary also provokes the appearance of this affection in predisposed persons. The nausea, weakness, and lypothymia felt by certain individuals on looking down from the height of a precipice, or of a column, or when they mount near the summit of a high mountain, are indicative of pathological states analogous to seasickness. We see, therefore, that the expression *naupathia*, or seasickness, is too restricted to designate an affection which manifests itself in conditions so varied, and it is desirable that a term more scientific and more general be chosen in medical nomenclature to designate the morbid state in question.

Naupathia can not be considered a microbic disease, as one writer would have it,* who imagined a "marine miasm" to be the cause of the sufferings of travelers on the sea. His hypothesis, however, is not supported by any kind of proof. One can not admit, therefore, that this affection is infectious or contagious, which excludes the possibility of epidemics, properly speaking, of naupathia.

Meteorological conditions have no determined influence in the production of this affection. No age is exempt from it unless it be that of early infancy. At two years of age children may be seasick. The influence of sex is quite evident. It is especially women that are seasick. Below the age of puberty, however, this condition loses its influence. Young girls are not oftener sick than young boys. The

explanation of this peculiarity is found in another part of this treatise.

The temperament of the passenger, his force of will, have really but a slight effect in warding off an attack. A much greater safeguard is the great interest in the voyage itself as felt by a person taking an ocean trip for the first time. The keen enjoyment of the novelty of the unusual surroundings has often kept a person from seasickness who on later voyages was numbered among its victims.

Other conditions favor the development of this trouble. Thus, the smallness of the ship or boat, the situation near either of its extremities where the motion of elevation and descent (pitching) is greatest, disagreeable odors, the sight of dirty kitchen utensils or of unappetizing dishes, and the possession of what is called "a delicate stomach" (although this organ is for nothing in the causation of most cases of seasickness)—all these things, we affirm, have a real ætiological influence.

Likewise the coexistence of certain other morbid states favors the development of naupathia. Thus persons having a catarrhal affection of the digestive tract, and especially those presenting a disease of the circulatory apparatus, are particularly exposed to an attack of seasickness. As an example of the first-named cause we recall the case of a sailor of the Dom Pedro who, in the middle of a voyage of twenty-four days, was ill of a catarrhal gastritis, and after a day or two later presented the characteristic symptoms of naupathia.

Cases of the second group are frequent, and insistence should be made in regard to the active rôle which cardiac affections here play. Valvular and orificial lesions of the heart; dilatation, steatosis, and fatty coating (*surchargé graisseuse*) of this organ, and its hyposthenia from whatever cause, are powerful predisposing causes in the production of this affection. We have seen a very obese lady whose heart beats were rather feeble, without other signs of hyposthenia or of other disease of that organ, and whose pulse tension was below the normal, in whose case one might properly suspect the existence of fatty heart, which lady has never taken a sea voyage without being seasick during the whole passage. Another woman having a pronounced mitral insufficiency suffered excessively from seasickness without getting any relief whatever from treatment that is usually efficacious. These examples could be multiplied, but they are sufficient to show the relation that exists between naupathia and any disease of the circulatory apparatus that destroys the physiological equilibrium of the circulation.

It is by no means necessary, however, that a *lesion* be present in some part of the circulatory apparatus in order that the affection which is under consideration be produced. A *functional perturbation* of the circulation is also adequate to produce it. It thus happens that such a large number of children and young persons of both sexes (who certainly have not all a cardiac or other disease) become sick during the first hours of a voyage, or of a spell of rougher weather than usual. It should be remarked that among the organs of circulation there should be included the sources of *innervation* of the heart and vessels—that is

* Sémanas, 1850.

to say, the crura cerebri (Meynert), the pons, the medulla oblongata, the spinal cord, and the ganglionic system of the great sympathetic, all of which are centers of cardiac or of vaso motor nerves. Therein lies a point of major importance in the therapeutics of naupathia, as will be shown a little further on.

There are, of course, many other states and conditions that predispose to naupathia. They may be summed up in the statement that in general (but not always) the states or the affections that enfeeble the forces of the organism render it apter to be seasick.

It has come to the writer's knowledge that certain individuals who were habitually sick at sea during voyages taken in youth and middle age gradually lost this tendency to seasickness during their advanced years. To what may this immunity be due? From our investigations in seasickness, we are convinced that the true explanation of this immunity is found in the growing inelasticity of the arteries as age advances and in the increasing insensibility of the various organs and tissues to the different excitations which figure as the causes of naupathia.

B. *Theoretical Part.*—The enumeration of the above facts is quite insufficient to satisfy the legitimate desire to know what is, after all, the real and ultimate cause of seasickness. The different causes just mentioned do not explain to us the nature of this trouble, do not give us a glimpse of the bottom of the case. Thus many an attempt has been made to reason out the matter and to discover if possible the pathological process itself and to understand how it is that the voyager, perfectly well one moment, is transformed into a sick person in the short space of a few minutes or a few hours.

There have been many other observers who, even centuries ago, have sought to explain this action of the sea. Hippocrates had his opinion of this also, but the theories of our times are more ingenious, if they are not more satisfactory, than that of this author. Thus Darwin affirms that "seasickness is due to vertigo," which, however, is no explanation at all, for the vertigo is part of the affection, being one of its chief symptoms.

Wollaston, with his "barometric theory" of seasickness, divined something of the truth perhaps; but he does not quite satisfy us.

Pellarin* goes further and says: "Seasickness is essentially determined by the influence exerted upon the circulation of the blood by the movements which the body undergoes and which have for principal effect the lessening of the ascending force of the blood in the aorta and in the arteries springing from the aorta, whence results a hyposthenic state of the brain from anæmia. The insufficient excitation of the cerebral organ immediately determines, by sympathetic channels, contractions of the diaphragm which provoke vomiting, of which the salutary effect is to cause a reflux to the brain of the blood which was lacking." This, we think, is true as far as it goes, but is incomplete and insufficient as an explanation. It confirms, however, our own ideas about the temporary utility of frequent emesis.

Autric* believed he could incriminate the cephalo-spinal liquid. According to him, this liquid would produce a shaking of the brain by the violent flux and reflux which it would make at each movement of the ship—a very ingenious theory, but too fantastical and improbable. It is rather surprising, though, to notice how almost every well-informed writer on naupathia mentions it, some to uphold and defend, some to hold in doubt, but most to repudiate. In verity, how should this beneficent liquid, placed by kindly Nature as a cushion around the central nervous system, become in turn a veritable battering ram to cause such misery on the sea? How could this scanty fluid pass through its narrow channels of communication with volume and force sufficient to produce the shocks or disturbance attributed to it? Compare the quantity of this liquid with the quantity of blood in the brain and spinal cord and observe how little it is; compare the lumina of the connecting passages for the liquid with the open calibers of the turgid blood-vessels, and decide through which class of channels the "flux and reflux" could occur most easily. We do not lose sight of the dynamic difference in the two fluids while making the above statement. One is in active movement while the other is not; both, however, are under a certain degree of pressure. It is more rational, if one wishes to make seasickness due to some lack of equilibrium in the fluids of the encephalon, to attribute it to the blood rather than the cerebro-spinal liquid.

Gillechrist (1774) (‡), Sper, and Larrey have supposed that seasickness was due to cerebral commotion produced by the oscillations of the ship.

According to Kéroden, "the movements of the ship cause disturbance in the play of the diaphragm and of the abdominal organs which are subject to collisions quite suitable to produce the spasmodic state and the convulsions of the stomach. The irritation of the phrenic nerves causes the diaphragm to contract. The ramifications of the pneumogastric and of the trisplanchnic nerves of the semilunar ganglia, likewise subject to these oscillations, react upon the stomach, the intestines, and the whole organism." These notions are not entirely conformable to the teachings of physiology, for the stomach does not play the principal rôle in the act of vomiting, as Magendie has so well demonstrated. Moreover, they do not explain very clearly the pathogenesis of the trouble.

Chapman† has published an opinion contrary to that of Pellarin, cited above. He believes rather in an abnormal afflux of blood to the posterior part of the nervous centers, and especially to those segments of the spinal cord that have relations with the stomach and with the muscles that have to do with vomiting. Still the same idea! They wish to make the stomach guilty of causing seasickness. It may have accomplices, so to speak, but still it is the most to blame. The stomach, nevertheless, has little to do with the production of naupathia.

One author will have it that irregular and insufficient respiration is the cause of seasickness. Therefore he would have his patients practice deep and regular breathing.

* *Comptes rendus de l'Acad. des sciences*, 1847, t. xxiv.

* *Montpellier thesis*, 1868.

† *Functional Diseases of the Stomach*, Part I, London, 1864.

Another believes the cause to lie in a disturbance of the muscular sense. The most far-fetched and pedantically expressed theory of the ultimate cause is that of Rosenbach,* who says: "For the origin of the symptom-complex of seasickness molecular disturbances are to be made responsible." These molecular disturbances (purely hypothetical, for that matter—W. S.) are caused "through intense intramolecular vibration" or shaking due to the motion of the ship. Unfortunately for this theory, the author is not able to derive from it the slightest aid in treating the affection, and the physician and patient are left as helpless as before.

Many American writers, such as the late Dr. Fordyce Barker, the late Dr. George M. Beard, Dr. J. Leonard Corning, and others, have devoted interesting articles to the subject of seasickness.

Having thus outlined the principal theories that other authors have advanced as to the remote cause and intimate nature of naupathia, let us describe still another one which, though new and entirely original with the author, has already been productive of rich therapeutical results. In other words, we will here expose our conception of the pathogenesis of seasickness that, followed to its logical conclusion, has indicated a mode of treatment unusually successful.

At the time this theory was accepted, after a thorough and independent study of seasickness, we were wholly unaware of those of other observers, for our researches into the literature of the subject were not made till long after our theory had been put into practice.

It is to be stated as an initial proposition that *the principal symptoms (q. v.) of seasickness, if not all, depend (1) upon an abnormal state of the circulation of the blood; (2) upon an abnormal state of the nervous system.*

Certain of these symptoms (vomiting, acceleration or slowing of the cardiac pulsations) are attributable to *anæmia of the medulla oblongata*; others (prostration, vertigo, and feeling of great distress) to *anæmia of the brain*; still others to *anæmia of the skin*; the oliguria, to a diminution of blood pressure in the kidney. On the other hand, the constipation, the feeble resistance of the pulse, and probably also the variation in the number and in the force of the heart beats, indicate *the diminution or the absence of action of the sympathetic nervous system* upon the unstriated fibers of the intestine and of the arteries, and also upon the intracardiac nerve ganglia.

This question of the *anæmia of the nervous centers* is interesting, but is one which at first sight is not easily explainable. Does there exist in naupathia a general *anæmia of the whole organism*? We think not. How can it be admitted in effect that a person who only a few hours before becoming seasick was enjoying perfect health, who might even have been plethoric, could suffer in so short a time a change in the quantity or quality of his blood, so that one is forced to believe in the existence of a veritable *anæmia of the whole organism* in the ordinary sense of the word?

It is a supposition evidently inadmissible. It can not be admitted that there is notably less blood in the body of a seasick person than there was in his body a few moments or a few hours before, when he was not yet sick. Therefore the quantity of hæmoglobin and the number of globules remain the same. How explain, then, the symptoms commonly attributed to *anæmia of different organs*? Without wishing to deny in any way the existence of this kind of *local anæmia* of the nervous centers, we feel able, on the contrary, to affirm and to explain its presence by attributing it (as we have already hinted) to general disturbances of the circulation of which they constitute but a feeble part. These disturbances we are about to study.

1. *The cause of naupathia is a general lowering of the arterial blood pressure.*

This conception of such a great disturbance of the circulation very naturally explains the oft-mentioned bulbar *anæmia*—i. e., *anæmia of the medulla oblongata*. If the medulla is *anæmic*, it is because the arterial pressure is not strong enough to fill and distend its arteries and arterioles. But all the other parts of the nervous system are also in the same condition. We have here a sufficient cause of the feebleness and inactivity of the centers of innervation of the heart and the blood-vessels. These centers are poorly nourished; they can not, therefore, perform their functions well.

We base this opinion (lowering of the blood pressure) upon the abnormal depressibility of the pulse, the coldness of the extremities, the oliguria, the paleness of the skin, also upon the extreme prostration and the feeling of "goneness" to which the seasick are subject, and upon the vertigo and cephalalgia that are among the symptoms of cerebral *anæmia*.

2. *The cause of the lowering of the arterial blood pressure is the feebleness of the heart's action, and probably also the slight dilatation of the sanguineous vessels, especially the arteries.*

When there is lowering of intravascular pressure in a vascular system, elastic and closed at all points, as is the circulatory apparatus in man, this lowering can only be due to two conditions: (1) Diminution of the contents of that vascular system, and (2) enlargement of the container, in this case of the vessels. The diminution of the contents of the arteries may result from (a) an arterial hæmorrhage; (b) the passage of the blood into the veins; (c) a lessening influx of blood sent from the left ventricle—that is to say, hyposthenia of the heart or cardiac insufficiency. In seasickness the first of these possibilities (a) should, of course, be excluded, but the third (c) ought to be considered as having a real influence. The enlargement of the container may result from (1) the dilatation of blood-vessels—above all, of the arteries; (2) the expansion and congestion of those organs that serve as reservoirs for the blood, and which are, among others, the spleen, the liver, and the intestine (Brücke). We shall see that these two factors may also be encountered in naupathia.

There are thus presented at least three causes for producing the lowering of the blood pressure. The cardiac hyposthenia is revealed by the feebleness of the heart beats

* Zur Lehre von der Seekrankheit. *Berl. klin. Woch.*, 1891, xxviii, 260, etc.

and by the abnormal depressibility of the pulse. As for the other two (dilatation of the blood-vessels, afflux of blood into the spleen, liver, and intestines), the direct proof of their existence is not easy to give; but the following considerations show how highly probable it is that they do exist. It will be demonstrated in a moment that the sympathetic nervous system which regulates the tonus of the arterial system (Cl. Bernard, Vulpian, Brücke) is paretic, whence the probable enlargement of the caliber of the arteries. On the other hand, Brücke declares that the vascular territory of the chylopoietic system (intestinal walls) is extensive enough to contain nearly all the blood in the body, whence the possibility of the lowering of the blood pressure by a kind of stagnation of the blood in the chylopoietic system.

3. *The cause of the enfeeblement of the heart's action and of the probable dilatation of sanguineous vessels is the paresis of the cardio accelerator and vaso constrictor nerve centers.*

It is universally admitted that the pneumogastric nerve possesses an inhibitory action upon the movements of the heart by intermediary of the intracardiac nervous ganglia. This is the *inhibition reflex*, so called by Bidder. It is also well known that the cervical portion of the great sympathetic exerts an accelerating action upon the heart. The excitation or stimulation of the nerves issuing from this portion of the ganglionic nervous system raises the blood pressure and increases the frequency of the pulse (Brücke). *Per contra*, when these nerves are paralyzed (by reflex action, by insufficient nutrition, or by other causes) the contrary phenomena are observed. It merits mention that Ludwig and Cyon have demonstrated that these two conditions (elevation of blood pressure and augmentation of frequency of the pulse) may each be independent of the other.

There are, however, other regions of the nervous system that possess a motor action upon the vessels. The principal center—motor and reflex—for the vascular system as a whole is found in the medulla oblongata (Schiff, Goltz, and others). But this vascular center extends along the whole height of the pons Varolii and even into the cerebral peduncles (Meynert). When this center no longer exerts its normal action upon the vessels, these suffer passive dilatation, whence follows a lowering of the blood pressure.

I have already admitted the existence of anæmia of the medulla and of all the cephalic and cervical nervous centers. Owing to the very fact of this anæmia, the vascular centers in those regions are insufficiently nourished and can not therefore accomplish their normal functions. It is the same thing for the cardiac accelerator center. It is by default of excitation from these centers that the heart does not beat so forcibly or so frequently and that the vessels allow themselves to be passively dilated. In cases of naupathia in which the cardiac pulsations are increased in number this abnormal frequency should be attributed to a co-existing paresis of the pneumogastric.

I have thus endeavored to establish my point which constitutes the third link in the chain of sequences present in seasickness.

4. *The cause of the paresis of the cardio-accelerator and*

vaso-constrictor centers is a reflex inhibitory influence exerted upon these centers, and originating either in the sensorium or in organs unequally and alternately pressed and pulled about by the movements of the ship, or finally in the walls of the blood-vessels themselves.

It was seen in the preceding paragraph that the anæmia of the nervous centers is a cause of their paresis. But this cause acts only when seasickness is actually established. The first and initial cause of this paresis should be sought elsewhere, and we can not consider it other than a reflex act of which the starting point is variable.

This reflex act, it has been said, may originate in the sensorium. It is in this manner that we explain the appearance of nausea, and vomiting even, in idiosyncrasic individuals upon merely seeing a boat tossed about by the waves, or upon perceiving an odor that vividly recalls to their mind the bad smells and other unpleasant circumstances of a former sea voyage when they were sick. There is nothing extraordinary in this, for that matter, for everybody admits that these phenomena (nausea and vomiting) are of a reflex order, and that the starting point is very often the sensorium.

This reflex act may also have its origin in the nerve endings in the abdominal and other organs. Kéraudren had already expressed an opinion somewhat similar. It is very rational to admit, in effect, that the organs situated in the great cavity of the abdomen undergo displacements more or less extensive, or suffer from slight collisions or contusions which result from the violent motions of the ship. The numerous nerves distributed to these organs are thus pulled, stretched, contused, and excited, for the abdominal walls are not rigid and inelastic enough to prevent some displacement of these organs. Hence there can arise here a reflex act having as result the production of seasickness by the process above described.

It is doubtless in these data that is found the true explanation of the greater frequency of naupathia in adult women, in whom the abdomen is relatively more developed than in men, and in whom the abdominal walls have become laxer from one or more pregnancies. It results from this that the abdominal organs are less solidly held in place in their normal situation, whence the greater facility of their displacement with all its consequences.

It is possible that there is still another origin of this reflex act in question. Wollaston with his "barometric theory" of seasickness touched closely to this point, but we conceive it in a somewhat different manner nevertheless. We also believe, it is true, in the reality of the influence of the movements of the boat upon the course of the blood in the vessels—an influence comparable to that exerted upon the mercury in the barometer tube by the same movements, only this influence is much less manifested upon the blood than upon the mercury by reason of the difference in the specific gravity of the two liquids. In fact, the column of blood in an artery, as the column of mercury in the barometer, exerts its strongest pressure on its containing walls (artery or glass tube, as the case may be) at the moment when the part of the ship occupied by the patient or by the observer sinks to its lowest point in the movements

of pitching and tossing. In other words, as the ship sinks to its lowest between the waves in a violent movement of descent, then the blood, having acquired a positive momentum downward, exerts more pressure than usual upon the walls of the blood-vessel containing it. This extra pressure tends to dilate the blood-vessel, or else actually does dilate it by force, especially if it is situated in the middle or inferior parts of the body. This condition could also be a starting point of the reflex inhibitory act.

It is easy to understand the action exerted upon the different organs and liquids of the body by the movements of the ship when one observes what occurs in cases like the following: On board of a ship, pitching in a heavy sea, a person is seated in a deep chair having easy spiral springs in the bottom. When the ship moves rapidly in a vertical plane, the person seated in the springy easy chair follows a movement which is not exactly that of the ship. In certain parts of the trajectory the person rises or falls with greater speed than the ship itself does. For instance, during the rise of the ship, especially during the second half of the rise, the person feels himself lifted or pushed up as though about to be shot out of the chair. He has the feeling of a sudden diminution of weight. The spiral springs lengthen out, and the occupant of the chair is actually elevated to a level higher by several centimetres, compared with surrounding objects—tables, windows, etc.—than that which he had an instant before. His back shoots up a little further above the back of the chair than it did before the ship started upward. At the end of the rising of the ship this independent movement on the part of the person ceases, and the two different rates of speed unite little by little, so that both the ship and the person in question arrive at the same instant at the maximum height of their respective courses. A similar difference in the speed of the two objects takes place during the descent of the ship into the hollow of the waves, only in an inverse direction. Now the person sinks more deeply into the soft bottom of the chair as the ship falls. Toward the end of the descent the person feels himself settling harder into the springy seat, as if his weight had suddenly increased or a heavy hand was pushing him downward. Quite at the end of the descent, as for the rise, the habitual equilibrium is re-established and the two movements are blended again. This is repeated at each upward and downward plunge of the ship, and the degree of intensity with which this takes place depends upon the violence of the ship's movements. The phenomena just described are real, as any traveler on a rough sea can testify. A person lying in bed during a storm experiences similar movements. Inanimate objects are seen to do the same thing when on springs. Mercury in a barometric tube acts in the same manner.

In regard to mercury in a barometric tube we have undertaken a few experiments to note the rapidity with which the translation of the quicksilver takes place. Interesting results were obtained. The apparatus consisted simply of an ordinary straight glass tube, thirty-six inches long, hermetically sealed at one end. This tube, which had a caliber of an eighth of an inch, was filled with mercury and inverted into a bottle containing mercury, no air being

allowed to enter the tube. When the tube was put vertically with the sealed end upward, there formed the usual Torricellian vacuum of five or six inches in height. The apparatus thus completed was carried to the extreme stern of the ship, where the rise and fall were the greatest during rough weather. It was found that under these circumstances the mercury was animated by very lively movements. As the ship sank into the hollow between the waves the mercury would also start to sink at the same time. The speed of the latter would increase rapidly as the ship was reaching its lowest point; then both the mercury and the ship would come to rest at the same instant. By this sinking of the mercury the vacuum would be lengthened by two or three inches according to the violence of the ship's descent. When the ship rose, the quicksilver would also rise, increasing in speed as it neared the top of the tube. When the ship was at its highest, so was the mercury, and sometimes its momentum had become so great that the vacuum was wholly obliterated, the mercury striking the top of the tube with a sharp click. It will be noticed that this movement of the mercury corresponds exactly with that of the person in the springy chair just described.

With the experiments of the barometric tube in mind, it is easy to admit that the blood in its vessels, especially in such as run more or less in a parallel manner to the long axis of the body, also is affected by an influence of the same kind, although not to the same extent. It can not be supposed that a vacuum is created in any part of the vascular system, but there is certainly the *tendency* to form one when the ship sinks rapidly, and this tendency must certainly impede the circulation to some extent and tend somewhat to expand the elastic vessels.

These facts in connection with the springy chair or bed and the barometric tube are very easy to observe, but it remains to explain them, to know their effects, and to apply them to the study of the pathogenesis of naupathia.

We explain them by supposing that during the first half of the upward or downward movement of the ship the mobile objects mentioned (person in the chair, mercury in the tube) have acquired a certain momentum which causes them to be displaced more rapidly during the second half of the oscillation in the same direction. This displacement would fail to take place if the person, for instance, sat upon an unyielding seat or stood upon the floor. But it must not be forgotten that the same forces are still at work, and that they affect whatever there is about the body that is not rigid. It is thus that the abdominal organs, being not absolutely immovable in their respective positions, are subjected to movements and to displacements comparable to those presented by the person in the chair. More than this: In the physiological laboratory of the Sorbonne, in Paris, M. Dastre has shown by actual experiments on the lower animals that movements like those of a ship actually do cause the abdominal organs to be shaken about, displaced, and their means of fixation strained. Here, then, is positive evidence of a source of irritation to the nervous system.

We see, therefore, that the various organs of the body

may undergo these contusions and collisions, as Kéraudren affirms; that the blood may be hindered in its course, as Wollaston suggests; and we wish to repeat that these phenomena may be the starting point of a nervous reflex act that, according to the chain of causes and effects above described, results at last in the production of seasickness.

5. *There exists in naupathia, once established, a veritable circulus viciosus, which explains the tenacity of the affection and its resistance to divers methods of treatment.*

This vicious circle is thus constituted: The seasickness being in full development with its habitual retinue of symptoms, there had previously been produced (as was demonstrated) a lowering of the arterial blood pressure, by virtue of which the nervous centers do not receive the full quantity of blood necessary to the perfect functioning. These centers, among which are the cardio-accelerator and the vaso-constrictor centers, being insufficiently nourished, can no longer react against the lowering of the blood pressure, and since this lowering is the immediate cause of the naupathia, the organism is thus unable to bring this state of things to a close, which state, without the efficacious intervention of the physician's art, will last indefinitely. It is only when the organism becomes gradually habituated to its new surroundings that it returns little by little to its normal state, or else the end of the voyage puts an end to the causes of the affection.

In *résumé*, here are the different steps *de initio ad terminum* of the process, as we understand it, which engenders the complexus of phenomena known as seasickness: Movements of the ship about one, at least, of its axes; movements, slight or considerable, and repeated displacements, collisions, and stretchings of various organs of the body, especially of the abdominal organs, and unequal and alternate increase and lessening of the pressure exerted by the columns of blood upon the walls of the arteries and veins; reflex nervous act starting from the displaced and strained organs and from the walls of the blood-vessels, and acting by inhibition upon the cardio-accelerator and vaso-constrictor centers; paresis or paralysis of these centers; consecutive loss of the tonus of the vessels and relaxation of the walls of vessels of medium caliber, and frequently diminution of the number of cardiac pulsations, whence results a *lowering of the arterial blood pressure*; establishment of a vicious circle, which places the organism in the impossibility of issuing spontaneously and immediately from this morbid state; finally, appearance of the external signs denoting the complete development of naupathia.

The great sympathetic nervous system is the most important factor in the production of this affection. Its inactivity paralyzes the muscular tunic of the intestine, whence the constipation; paralyzes the radiating fibers of the iris, whence the myosis; paralyzes the accelerator nerves of the heart (at least in men and in half the women) and probably also the vaso constrictor nerves of the blood-vessels, whence the lowering of the blood pressure with all the symptoms that depend upon it; it favors by its paresis the production of pytalism, as certain experiments of Czermak, Eckhard, and Grützner demonstrate. One might

really affirm that *all the symptoms of seasickness, without exception, are explained by attributing them to a paralysis of the grand sympathetic.*

We have already defined the place that this affection should occupy in medical nomenclature.* It hardly merits the appellation *disease* any more than syncope does, with which it has several characteristics in common. It is not caused or accompanied by any known anatomical lesion; it is only the expression of certain functional or dynamic troubles. It has therefore no pathological anatomy; its pathological physiology is sufficiently described in the preceding paragraphs. Morbid affections without known lesions are generally classed under the name of neuroses. It seems, therefore, that naupathia ought also to be considered a neurosis, and, according to the eminently preponderant rôle that the sympathetic nervous system plays in this affection, it ought to be regarded as a *neurosis of the great sympathetic*. Thus classed, it would be the most important of all the known neuroses of that part of the nervous system.

(To be continued.)

FOUR YEARS' WORK IN DISEASES OF THE RECTUM

AT THE POST-GRADUATE HOSPITAL CLINIC.

By CHARLES B. KELSEY, M.D.

It is just four years to-day since the attempt to give systematic clinical instruction in diseases of the rectum was begun at this college. I remember well our first and only patient on that day—a man who was convinced that he had a stricture of the rectum because he was constipated and because a bougie caught upon the promontory of the sacrum. Many such have been shown to the class since.

In the four years we have had five hundred and seventy-eight cases (no case being entered twice for the same disease), and we have operated two hundred and ninety-two times before the class. A few of the more common affections of the rectum and anus make up a majority of the cases, but there is scarce any disease in any way relating to these parts which you have not had a chance to study more than once. For example, there have been 192 cases of hæmorrhoids, 72 of fistula, 61 of non-malignant ulcers and strictures, 39 fissures, 35 cancers, 29 cases of pruritus, 28 of prolapse, 26 of abscess, and 17 of polypus, making 502 out of 578 cases; but the balance includes perhaps those of greatest interest, covering as it does congenital malformations, 5; pelvic abscess, 5; incontinence of feces, 5; intussusception, condylomata, coccygodynia, acute proctitis, foreign bodies, impaction, neuralgia, and the cases of simple intestinal catarrh with the symptoms of diarrhoea or constipation so frequently sent to us for examination either for supposed ulceration or stricture.

The list of operations is made up as follows: Hæmorrhoids, 90; fistula, 40; fissure, 24; abscess, 20; colotomy, 31; extirpation, 11; proctotomy, 7; ulcers, 19; polypus,

* W. W. Skinner. The Place that Naupathia, or Seasickness, should occupy in Nosology. *New York Medical Journal*, 1889, xlii, p. 626.

12; prolapse, 20; faecal incontinence, 4; proctoceles and lacerated cervix, 2; pruritus, 6; intussusception (laparotomy), 1; pelvic abscess, 2; congenital malformation (plastic), 3.

In the ninety operations for hæmorrhoids the clamp and cautery have always been used, and there has been no case of hæmorrhage, stricture, or other accident of any kind whatever, and no case of recurrence. The average length of time in bed has been forty-eight hours, and in hospital less than one week. You all know how common it is to see these patients up and walking around the wards two or three days after the operation, and how difficult it is to keep them here till the expiration of the first week in order to show them to the class. The house staff know how rarely any anodyne is given and that the use of the catheter is almost unknown. These cases are operated upon, moreover, without any preparatory treatment of any kind. They come into the house an hour or two before the clinic, are etherized and operated upon, and for about two days are kept in bed. At the end of that time the bowels are moved by a laxative, and the patient begins to want to leave the house. Rarely does one remain more than a week. Some of them report as out patients at the end of the second week; many are never seen again. This general history has been repeated nearly a hundred times before you in the last four years, and because these results are the ordinary ones and can not be approached by any other method of operating, we always use the clamp and cautery, and shall continue to do so till something better is found to replace it.

It is only fair to say, however, that the success of this method depends, like most other operations, a great deal upon the manner in which it is done. Although the operation is exceedingly simple, and can easily be completed in a case of extensive disease within a couple of minutes by a practiced operator, it is just as easy for an unskillful operator to cause great after-pain, sloughing, and hæmorrhage. It has come to my knowledge that in one part of the country the operation fell into great disrepute because of the after-pain and sloughing. Having, after considerable persuasion, myself operated upon one of the best of the unsuccessful operators, he was equally pleased and surprised at the entire absence of any bad symptoms. He could not understand the cause of the difference till he went with me to see yet another case, when, after a few seconds, he exclaimed, "I see it all!" It seems that, instead of pulling the hæmorrhoids outside of the anus before removing them, these gentlemen had been carrying the clamp and then the cautery within the bowel, and applying them to the tumors *in situ*.

Another example occurs to me. At a clinic in New York, although this method is generally followed, the operator always fills the rectum after the operation with a vulcanite tube wrapped in iodoform gauze. At the Post-graduate Clinic no dressing is ever used except a pad and T-bandage for an hour or two. It would seem as though to first remove the piles and then plug the anus with a generous roll of gauze might cause a good deal of after-pain. If the cautery is properly used, the plug will never be necessary.

This is not the place, however, to describe the details of the operation. The results are given simply. These results can be obtained by anybody who has once either seen the operation performed or grasped its technique from a written description.

Of non-malignant ulcerations and strictures there has been a large and varied collection, every variety known being shown and operated upon more than once. Perhaps the chief point of interest in them, outside of the question of treatment, is the difficulty generally met with in deciding upon their origin and pathology. No patient is ever accused of having had syphilis because he or she happens to have a stricture of the rectum; for, although we teach that syphilis is a possible cause of ulceration and stricture, we believe it to be one of the least frequent, while in most text-books you will find exactly the opposite taught. When we do not know the exact character of the morbid process there are many possible causes to be considered besides syphilis. Simple varicose ulceration of the rectum, or ulceration due to slight traumatism, will account for many cases. Many, I confess, are difficult to classify, but because we can not tell with certainty we are not justified in lumping them together as syphilitic, especially as we know nothing about what the morbid process is or how it begins which is supposed to cause the so-called "syphilitic stricture," and as there is often no history or trace of any other manifestation of the disease. There is a chancroidal ulceration of the rectum and also a tertiary syphilitic ulceration, both of which may cause stricture. But both of these are so rare you will probably never see them, and the time for classifying all strictures not malignant as due to a process which has never been understood, but which has been much written about under the title of "ano-rectal syphiloma," has gone by. Therefore we classify the cases as tubercular, dysenteric, traumatic, varicose, lupoid, and venereal, as the history and appearances may decide, but, when we do not know, the case is put down as doubtful and not as syphilitic.

In the treatment there are three different methods—local applications with or without proctotomy, colotomy, and extirpation. It is only the slighter forms of the disease which can be benefited by cauterization, division of the muscular tissue, rest, and diet. Most of them, after they have existed for any length of time and have done their destructive work, are incurable by any means short of colotomy or extirpation. When the disease is low down and when we are sure that it is confined to one spot which can be reached, we may be inclined to extirpate it; in other cases a colotomy is indicated.

In passing, there is one other point which may be of interest. What is the authority for the universally accepted statement that this affection is much more frequent in women than in men? In our experience here, as in private practice, we find the disease equally divided between the sexes.

The thirty-one colotomies show the wide range of applicability of the operation, having been done for imperforate anus, old pelvic cellulitis with abscess and pressure on the gut from plastic exudation, non-malignant ulcera-

tion both with and without stricture, rectovesical fistula, for destruction of the gut due to old hip-joint disease, and for cancer. The majority of these operations have been eminently satisfactory in accomplishing the end desired—the relief of pain and prolongation of life. Occasionally an opportunity occurs to show you one of the cases after two or three years have elapsed. A few weeks ago you had a very striking clinical illustration of the advantages of the operation given you by the surgeon from the West, a member of the class, upon whom I operated two years ago for simple ulceration. His own account of himself was of much greater value than anything I might say about him, and he asserted that he was perfectly comfortable and able to attend to a large practice without the least annoyance from the artificial anus. The ulceration for which the artificial opening was made had entirely healed, but the rectum was much contracted and he did not care to take any risks to have the new anus closed.

There is one point worthy of attention in this connection. In operating for cancer you can promise a great deal, but not everything. Although the patient will almost invariably gain fifteen or twenty pounds of flesh in the first few months and will improve greatly in every way by the absence of the rectal tenesmus and the ability to sleep, he will still suffer from the cancer itself. At first you may hear some complaints that he still has pain in the back and loins, and that he still has to go to the closet once or twice in twenty-four hours to relieve the rectum of a little blood and slime. These two troubles you may never be able to stop; and yet while the patient is complaining most bitterly of them he is apt to tell you, if you ask him, that he has decidedly gained in health and strength, that the artificial anus is the cause of no particular annoyance, that he sleeps well at night, and eats as well as he ever did. As the time goes on and life is prolonged from weeks to months and even to years, his appreciation of what has been done for him will also increase.

We have had our fatal cases also—three or four of them. In hospital practice, especially where cases are operated upon in the last stages of exhaustion and intestinal obstruction, some will die shortly after the operation who would have died just as soon had they not been operated upon. I remember but one case among those I have put down as fatal where it could properly be said death was directly due to the operation itself, and that one should not have been lost. The others have been cases in which the operation has simply been done too late to save life, and the patients have died in spite of it rather than because of it.

The rule followed here in the treatment of cancer of the rectum is almost invariably to operate as soon as the patient's consent has been gained, either by colotomy or one of the methods of extirpation. In the cases suitable for extirpation we do it; in the vast majority of the others the patient will live longer for a colotomy. There are exceptions to this, and a cancer may exist which can not be removed and which does not call for an immediate colotomy; but such cases are a very small minority—not more than one or two per cent.

The eleven cases of extirpation have all been for malignant disease. In the one case begun for non-malignant stricture the disease proved so much more extensive than was anticipated that not even Kraske's incision sufficed to give us room, and the operation was abandoned, no harm resulting from the attempt.

In extirpating, the incision is used which gives sufficient room for the purpose. The old perineal incision we have practically abandoned, because even in disease sufficiently near the anus to be reached in this way, a short dorsal incision with preliminary removal of the coccyx gives a much better field for removal of the lower end of the gut. By this incision, instead of rushing the operation, as is necessary when cutting at the small end of a deep funnel amid profuse hæmorrhage, we can operate slowly and with great precision, securing each bleeding vessel as it is shown. This incision will suffice also for the removal of many growths without opening the peritoneum or cutting away the sacrum. If it should not give room it is easily prolonged upward and to the left, the sacral ligaments can be cut, the lower sacral vertebrae removed, and we have all the room possible to obtain.

Even with this incision there is a great difference in patients as to the ease with which the sigmoid flexure may be drawn down, depending on the attachment of the mesentery.

Perhaps the main difference between our practice as to extirpations here and in some of the general hospitals will be found in the choice of cases. Many cases are manifestly only suitable for extirpation, and in these the results are good. Many others with equal certainty call for colotomy, and here also the results are good. But in the cases on the border line—those in which an attempt at extirpation is justifiable, but in which an immediate recurrence seems to us more than probable—we always give the advantage of the doubt to the patient and do the operation of least danger and greatest certainty of relief—colotomy.

The one case of laparotomy for intussusception was not successful in prolonging life. The little patient was *in extremis*, the invagination having existed more than a week, and died about twelve hours after the operation. It was a case in which the diagnosis was easily made by the presence of the appendix and caput coli in the rectum.

In the very annoying and obstinate cases of pruritus ani we have obtained the best results from light applications of the cautery to the affected surface, preferring this to the free curetting with the sharp spoon as done abroad. Many cases have been cured in this way which had for years resisted milder forms of treatment.

The twenty operations for prolapsus have all been successful as far as we know. In the severe cases we rely upon the linear cauterization according to Van Buren's plan. In the milder ones we use the clamp as well as the cautery in much the same way as in operating for hæmorrhoids. Only one case has occurred in which it was thought proper to attempt resection of the prolapsed gut, and in that one the patient died of an intercurrent affection before the operation.

A METHOD OF RHINOPLASTY.*

By PARKER SYMS, M. D.

By this term is meant a plastic operation for the restoration of a whole or portion of a nose which is absent as the result of a destructive injury or disease or of congenital deformity. Hence is the very natural classification of rhinoplasties into complete and partial.

When the principal parts of the nose are absent, including the soft parts and the cartilaginous framework, even though the nasal bones are intact, the operation necessary for restoration belongs to the first class. Many ingenious and elaborate operations have been devised for this purpose. Extensive and peculiar flaps have been taken from various parts of the face, arm, hand, etc., by gliding, sliding, transplanting, and grafting; without the bony and cartilaginous support these flaps eventually become sunken to the level of the face, and all that has been accomplished is the covering up of the former cavity and space. To supply the lost support, a phalanx of a finger has been attached in site, the soft parts of the finger used to form the new nose, and after union had taken place the finger amputated from the hand, which had been held in place by means of a plaster splint. More recently an osteoplastic flap has been turned down from the forehead. I saw such a case last week in which a good bony bridge had been obtained. In the cases of complete or nearly complete absence of the nose no operation has yet succeeded in more than changing the character of the deformity and of improving to a comparatively slight extent the appearance of the patient. I have come to the conclusion that complete rhinoplasty is useless and that the patient will do much better to avoid the prolonged torture of oft-repeated operations, and the further deformity of other parts resulting from these plastic operations, and to wear an artificial nose. A nose made by surgical skill is always a ridiculous deformity, is always conspicuous and revolting, and never would be mistaken for a nose if it were situated in any other part of the body than the place where a nose should be. An artificial nose is much less conspicuous and is much more natural in appearance. Of course it is more or less troublesome to wear, though this objection is very materially lessened by ingenious devices.

When the essential portions of the nose are intact a very good result may be obtained by plastic operations, but always in inverse proportion to the amount to be restored.

These partial rhinoplasties should be as simple and as limited in extent as possible, for there is always a resulting deformity at the site from which a flap has been taken. Due consideration of this fact must be made, for the object is to improve the appearance of the patient and not merely that of the nose.

It is not my intention to describe the many forms of plastic operations on the nose, but to call attention to one very simple one, which will accomplish all that more elaborate and complicated procedures will, in cases in which

there is a considerable destruction of this feature. In these cases the only result to be expected is to supply the deficiency and leave as inconspicuous and natural a nose as possible.

The cases in which I have had experience in this operation have been cases of cancer in which more or less of the nose had been removed surgically and the flap operation done at the same sitting. The first one I saw was done by my friend Dr. Outerbridge, and I was so pleased by the simplicity of the operation and by the ultimate result that I have been glad to adopt it.

In these cases the septum was not destroyed, but a considerable portion of the soft parts had to be removed.

The operation consists in making a single flap on the diseased side by two parallel incisions made as far apart as the space to be filled is wide. The incisions go through the skin and its fascia; they are carried far enough to allow the flap to be drawn to the further margin of the space without much tension. The flap is then stitched in place and to the skin margin throughout the entire length of the incision. This flap is entirely analogous to the one made in Malgaigne's operation for the formation of a new lip. If the lower part of the nose is the seat of the operation, the incision may be made perfectly straight from the nose, for there the skin is very loose and will stretch readily. If it be difficult to get sufficient length of flap, the incision should be curved downward almost at a right angle and the flap pulled out straight. Should there be some puckering of the skin on the face in suturing the flap to it, it will be owing to the fact that the flap is shorter than the skin margin. This is to be overcome by removing a triangle of skin at the outer end of the incision, its base being the line of the incision; then suturing the sides of the triangle together will shorten the skin margin. If the anterior surface or both sides of the nose be involved, a similar flap should be made on each side of the face and their ends sewed together so as to completely cover the nose.

In cases of cancer, recurrence is so apt to take place that an elaborate rhinoplasty would not be justifiable even if the result would be a natural-looking nose. The operation which I have just described is very simple, can be done quickly, and the result so far as appearance is concerned compares very favorably with that of other and more complicated methods.

The Suprarenal Capsules in Pyocyanic Infection.—"M.M.

Langlois and Charrin, observing with regret that in bacteriological investigations the suprarenal capsules are very rarely examined, or if so only macroscopically, have endeavored to remedy this defect in their investigations on pyocyanic infection. They report that the suprarenal capsules of guinea-pigs with acute pyocyanic infection were always enlarged and were darker on the surface than normal. The capillaries of the surface, too, were full and congested; the surface of a longitudinal section was dark. When the juice was sown on agar, pyocyanin appeared. After hardening, sections showed the central zone engorged with blood; the vessels were dilated and sometimes hæmorrhages could be detected. The tubes bordering on the central zone were enlarged and the cells contained colored granules."—*Lancet*.

ON SOME OF THE MANIFESTATIONS OF
SYPHILIS OF THE UPPER AIR-PASSAGES.*By J. H. BRYAN, M.D.,
WASHINGTON, D. C.

SYPHILIS affecting the mucous membrane which lines the upper respiratory tract manifests itself in so many different ways, and is of such interest to the surgeon, that a report of a few cases illustrating some of its rarer manifestations may be of interest to the association.

CASE I. *Syphilitic Stenosis of the Larynx*.—This was a particularly distressing one, occurring in a lady of high social standing, who acquired the disease through her husband. Owing to the difficulties in the way of getting a history of her trouble, the disease had steadily increased, making severe inroads upon her system before it was recognized. Before coming under my care it was stated that she had been treated for three years for tuberculosis of the larynx. When first seen by me she was greatly emaciated and scarcely able to walk without assistance. There was great difficulty in breathing and almost complete aphonia. She was greatly annoyed by a distressing cough, which was accompanied by an expectoration of a thick,ropy mucus. The paroxysms of coughing at times were so severe as to threaten life.

Examination revealed the mucous membrane lining the fauces, the larynx, and the pharynx to be of a very pale appearance. In the post-nasal space there was a large cicatrix on its posterior wall, the result of a former ulceration. The right half of the epiglottis had been destroyed by an old ulceration which had healed. The ventricular bands were infiltrated to such an extent as to almost completely obliterate the lumen of the larynx, leaving a very small opening posteriorly, which served for the passage of air and expulsion of mucus.

It was ascertained that some years ago she had had an eruption on her face, and had also suffered from rheumatism, for which she received treatment at the Warm Springs of Virginia.

Auscultation of the chest revealed numerous large and fine râles due to the pent-up mucus which the patient was able to expel only in small quantities.

A bacteriological examination of the sputa gave negative results.

The patient was urged to submit to intubation, with the belief that it was the readiest method of obtaining relief in her then critical condition, but at the earnest solicitation of her family it was postponed in order to give internal medication a fair trial. Accordingly, the patient was given a saturated solution of iodide of potassium, the dose of which, beginning with fifteen grains, was gradually increased to the point of tolerance, which was found to be eighty grains in the twenty-four hours. Within a few days the patient expressed herself as feeling relieved, the breathing became easier, and the cough and expectoration much lessened. The improvement continued, and in the course of two months the infiltration of the ventricular bands had so far disappeared that a good view could be obtained of the interior of the larynx and the upper part of the trachea. The vocal cords were found to be almost completely destroyed, and in the trachea were semicircular bands of cicatricial tissue as far down as could be seen.

The patient gained rapidly in flesh and strength, and in the course of six months she was able to walk several blocks without assistance. The dyspnoea, although still present, was

greatly reduced in intensity, and the voice, which was nearly absent, was so far restored that she could speak in husky tones.

I have recently seen this patient, who has been absent from the city for nearly two years, and her condition is much the same, the stenosis not having returned.

CASE II *Syphilitic Amygdalitis undergoing Suppuration*.—Mr. —, aged forty-five years, consulted me in October, 1891, for tonsillitis, stating that for several weeks there had been a great tenderness in the throat and difficulty in swallowing. A specific history was denied.

Examination showed intense congestion of the fauces with enlargement of the left tonsil, the latter presenting a grayish appearance on its free surface. The patient had not been under observation more than a week before a macular eruption made its appearance on the face, trunk, and upper extremities.

The amygdalitis advanced in spite of a vigorous mercurial treatment, and resulted in suppuration, the abscess pointing at the lower border of the tonsil, between it and the base of the tongue. About the same time there was a marked swelling of the left arytenoid cartilage and the corresponding aryteno-epiglottic fold, which so encroached on the lumen of the larynx as to embarrass respiration.

The mercurial treatment was abandoned, and the patient was given twenty grains of iodide of potassium three times a day; the result was a rapid subsidence of the swelling of the arytenoid cartilage and of the ary-epiglottic fold, and a complete disappearance of the inflammation of the tonsil.

This case is of interest as it illustrates the intensity of the poison, which was sufficient to produce suppuration, which is unusual in amygdalitis due to syphilitic causes.

CASE III.—*Congenital Syphilis of the Pharynx and Larynx*.—The family history of this case is instructive. It appears that the mother contracted a chancre on the lip from kissing her lover, whom she afterward discarded for her present husband, who has always been a healthy man. The chancre was excised, and no secondary cutaneous symptoms made their appearance. She had, however, some throat and bronchial trouble, which was relieved after a course of iodide of potassium. The result of the union was three girls; the eldest, between sixteen and seventeen years of age, has been an invalid for a number of years, bordering on imbecility. The second daughter is fifteen years old and is a fine-looking girl, who has thus far shown no signs of syphilis. The third daughter, the subject of this sketch, is now twelve years of age. When about nine years old she began to show signs of failing health. Both eyes were the seat of interstitial keratitis to such an extent as to cause almost total blindness. She also suffered at this time from deafness and an inflammation of the nose. Under the judicious employment of mercury by her oculist, Dr. Richey, who referred her to me, the opacity of the right cornea cleared up entirely and that of the left is rapidly disappearing. She recently came under my care for a severe sore throat and a persistent cough which prevented her from getting any continuous rest at night. Her condition was then as follows: The expression was one of anxiety, the complexion pale and waxy; the left eye showed slight interstitial keratitis, and the voice was husky. On examination, the nose was found to be filled with a thick muco-purulent secretion, which, when removed, showed a pale, thickened membrane lining its cavities. The teeth were regular and not notched. On inspection of the throat, a small ulceration was observed on the anterior surface of the soft palate, while in the post-nasal space there was a large ulceration extending down to the soft palate, involving the right posterior palatine fold, and which had destroyed the right tonsil. Ex-

* Read before the American Laryngological Association at its fifteenth annual congress.

amination of the larynx revealed an ulceration which had destroyed the right half of the free margin of the epiglottis, and an enlargement of the arytaenoid cartilages and ary-epiglottic folds to such an extent that it was impossible to get a view of the interior of the laryngeal cavity.

The patient complained of a constant pain in the region of the larynx, radiating toward the ears, painful deglutition, and an incessant cough with some dyspnoea.

The patient was given an antiseptic wash for the nose and throat and ordered five grains of the iodide of potassium three times a day, and tonic doses of mercury were continued. She began to improve under this form of treatment immediately, and in the course of three weeks the ulcerations in the pharynx and larynx had completely healed, and the swelling of the arytaenoid cartilages and the ary-epiglottic folds had subsided so that the interior of the larynx could be seen.

There has been some adhesion between the posterior palatine fold and the pharynx, with the result of narrowing the opening into the post nasal space. She does not cough and she has gained flesh rapidly.

While congenital syphilis may make its appearance at any time after birth, it is generally not so retarded as in the above case. J. N. Mackenzie * found, from an investigation that he made of this subject some years ago, that fifty-five per cent. of the cases occurred within the first year, and as many as thirty-three per cent. within the first six months. It occasionally happens, however, that its appearance is delayed until about puberty.

The disease may manifest itself in any form, but its most frequent manifestation is in deep ulceration of the soft palate, from which it extends to the hard palate and post-nasal space, showing a tendency to attack the bones, producing caries and necrosis.

The larynx, although frequently the seat of congenital syphilis, is not so often affected as the soft palate and pharynx, and, in the opinion of Bumstead,† it is always secondary to the pharyngeal lesions, the pharyngeal ulcerations preceding or coexisting with the laryngeal lesion. Mackenzie,‡ on the other hand, believes that the laryngeal lesion occurs much more frequently than is generally supposed, and he states that we may look for an invasion of the larynx in congenital syphilis with as much confidence as in the acquired variety.

The Iowa Board of Medical Examiners.—This board has ordered that on and after July 4, 1898, no medical school shall be considered as of "good standing," for the purposes of registration of its alumni within the State, unless it has a four-course curriculum. Each course of attendance upon medical lectures must be not less than six months long, and two courses in the same year will not be held equivalent to two courses.

Mathews's Medical Journal.—This is the title of a new quarterly, devoted to rectal and gastro intestinal diseases, to be edited by Dr. Joseph M. Mathews, of Louisville. It is announced that the first number will be issued as soon as possible after the first day of January, 1894.

GRATUITOUS MEDICAL SERVICES.

It is a time-honored custom among members of the medical profession for each one of them to render unto each of the others, and to the various members of his family, professional services without expectation of fee or reward in any shape. This is well known to all our readers, and is really an integral portion of the creed that every medical man cherishes. The exception only proves the rule. We regret to have to confess that a few instances have come to our knowledge of late years in which members of the medical profession, waxing sordid as they grew prosperous, have followed the practice of charging half-fees to their professional brethren; this they have done not timidly or covertly, but rather boastfully. Such a course of conduct we regard as wholly damnable. There is no member of the medical profession, however humble his position in life may seem to be, who may not some time have it in his power to make adequate return for medical services rendered to himself or to his family, either to him who has rendered them or to some one dear to him. Therefore, by all means let the prevailing custom be adhered to invariably until its abolition is openly resolved upon. However, while every physician expects to receive for himself and for his family the best professional services of any and every colleague, he does not in most instances rest wholly upon the chance, great as it may be, of his some time being able to return them in kind; it is customary for him, especially in cases of severe or long-continued illness, to offer a little gift to the professional brother to whom he is indebted, not necessarily of adequate intrinsic value, but expressive of his appreciation and gratitude.

On a par with physicians needing medical services for themselves or their families are the deserving poor in the community at large, and it is the pride and pleasure of every true physician to render to such persons the most assiduous care of which he is capable, without any expectation or hope of reward. To the credit of these persons be it said, they often recompense the physician by some gift, and the gift is cherished not in proportion to its costliness, its beauty, or its utility, but as representing a sentiment grateful to every upright human being. Of what is a young physician prouder than of some trinket to which, in the presence of a professional brother, he may point and say: "That was given to me by a 'g. p.'"—meaning a grateful patient? It must happen over and over again that patients are moved to give a physician some such testimonial, but hesitate either on account of being unable to decide upon a suitable present or by reason of dread lest the gift may be resented. Some such hesitation was lately expressed by a Brooklyn lady who unbosomed herself to the editor of the

Sun, to whom she wrote that she, being a married woman, but separated from her husband, had, together with her children, been treated by an unmarried physician, who refused to accept payment for his services. She added that she kept a small gentlemen's furnishing store, and asked the editor's opinion as to whether or not it would be proper for her to give the physician a present, and, if it was proper, what she should give him. The editor's answer to this lady's letter is one of the most graceful tributes ever paid to the medical profession. It runs as follows:

"We fully appreciate the delicacy of feeling with which this question is put to us. It calls our attention also to a praiseworthy feature of medical practice. Possibly physicians form the most truly charitable section of the community, not on the strength of that rule of professional etiquette which requires any practitioner to treat a brother's family gratis, but because of the very great extension of this habit to persons of no professional connection, for no other reason than that of downright, straightout kindness of heart. The medical profession is instinctively possessed of the sense that it holds to an unusual extent a trust for the benefit of humanity, and that scarcely any man can call on it in vain. It is eminently proper that this married woman should give some little practical expression of her indebtedness to this unmarried doctor. Friendship such as is due from her to him brooks no merely conventional restraint on account of the particular relations existing between the wife and her husband. The circumstances of the doctor's help and the happy time of the year both indicate a reward of some sort. Let there be a Christmas present by all means, though as to what it should be we can only suggest to our gentle friend, the shopkeeper, that while practical usefulness is never to be despised, yet human nature is such that, as the crude utility of a gift increases, sentiment is apt to decline in proportion."

TUBERCULOUS PERITONITIS CURED BY THE INTRA-PERITONEAL INJECTION OF CAMPHORATED NAPHTHOL.

We learn from the report of a recent meeting of the Hospital Medical Society of Paris, published in the *Union médicale* for October 31st, that M. Rendu presented a woman, twenty-five years old, whose health at that time appeared quite satisfactory. It was noticed that her abdomen was normal, supple, and free from ascites. The case was an example of recovery from tuberculous peritonitis. Last January she entered the hospital for a febrile erythema nodosum, and ten days later she left quite well. She returned on the 15th of May, pale, emaciated, and with a rather pronounced ascites. She had alternating diarrhœa and constipation, diffuse abdominal pains, and evening fever. Below the umbilicus a zone of dullness was perceived, shifting in accordance with her change of posture and fluctuation was clearly elicited. Above the umbilicus palpation gave the sensation of a diffuse pasty condition. The lower limbs were œdematous. The heart was normal. The urine was free from albumin. The liver was not enlarged. By exclusion tuberculous peritonitis with an insidious onset was

diagnosed. The pleuræ began to be affected; there was a little effusion in each, less abundant on the left side. Examination of the lungs revealed hardly more than a little harshness of respiration and a little increase of vocal resonance at the apex of the right lung. The patient coughed but little and did not expectorate at all. The pleural effusion confirmed the diagnosis of tuberculous peritonitis, for since M. Godelier's and M. Fernet's contributions it has been known, said M. Rendu, that the pleura is often attacked in consequence of tuberculous peritonitis.

Before proposing laparotomy M. Rendu, on the 22d of May, punctured the abdomen and withdrew about four fifths of the liquid, making about six quarts. Immediately after the puncture he injected into the remaining liquid five hypodermic-syringefuls of pure camphorated naphthol. During the two or three succeeding days the patient experienced dull pains in the abdomen; moreover, on the day following the puncture the temperature rose to 104° F., and she had nausea and a little diarrhœa. All these symptoms disappeared rapidly, and the ascites was not reproduced. After that, abdominal palpation gave the sensation of a diffuse resistance produced by agglutinated intestinal coils. About the 15th of June the subumbilical region became soft, but there was still to be felt in the region of the stomach a diffuse, irregular, nodular mass, which seemed to be constituted by thickened and indurated omentum. On the 15th of July the patient was fairly advanced in convalescence; a node, however, about as large as a nut was still to be felt in front of the stomach, but by about the 15th of August no traces of it remained and the abdomen was absolutely supple. During this time the pleural effusions had been completely resorbed. After that the patient's general health had remained excellent and she had gained weight and appetite. In short, she might be considered as absolutely cured. M. Rendu was therefore of the opinion that before a patient with tuberculous peritonitis was subjected to so important an operation as laparotomy it would be well to try intraperitoneal injections of antiseptic liquids.

MINOR PARAGRAPHS.

AIR EMBOLISM.

In the nineteenth of a course of lectures delivered by Dr. David W. Cheever, professor of surgery in Harvard University, and published in the *Boston Medical and Surgical Journal* for November 16th, we find the subject of air embolism treated of substantially as follows: One of the most distressing and rapidly fatal accidents that can occur in a venous wound is the entrance of air. It must be a large vein to admit it. It is sucked in in inspiration. That is the case in the larger veins about the neck, which have no valves, and is especially the case when the mouth of the vein happens to be held open after it is cut by being attached to a fascia, as about the neck, in the popliteal space, in the groin, etc., but especially in the neck. When, for example, the surgeon is engaged dissecting out a tumor in the subclavian triangle, everything is done more easily if the parts are on the stretch. The tumor is lifted to dissect it out; the parts beneath are on the stretch. They are out of sight

and very probably displaced by the growth of the tumor. The vessels may be enlarged as well as displaced by the long-continued pressure of the tumor. It is, then, easy to understand how it frequently happens that the surgeon, in dissecting out the tumor, cuts through the fascia and the wall of the vein; the patient, making an inspiration, draws air into the vein, and the immediate consequence is what is sometimes called air embolism—that is, the air rushes down into the right cavity of the heart and appears in some way to obstruct immediately the action of the valves, either by displacing the blood and causing a froth, or by churning up the blood; at any rate, the immediate effect on the heart is terrible and disastrous. The patient gasps, paleness and lividity come on, and death takes place in a very short space of time.

The best treatment, of course, is the preventive treatment, and there are two ways that may be used—either an assistant must be ready to thumb any vein, that may be opened, and keep his thumb right about the subclavian region while the operation is going on, or another expedient may be used, which is to keep the bottom of the wound thoroughly wet in a puddle of some antiseptic fluid. Either of these measures is a safe one.

When the accident occurs it is generally fatal. One or two bubbles of air occasionally go in and do not make enough trouble to destroy life, although there are temporary faintness and palpitation. The sound of the air entering is usually quite distinct. It is sucked in with a gurgle; the surgeon at once becomes conscious of the fact and compresses the vein, injects ammonia or brandy, promotes artificial respiration, and, in a slight case, succeeds in saving life, but not in the severe ones.

THE WISDOM TEETH AND THE TONSILS.

In the *Mercredi médical* for November 15th there is a paper which was read before the Bordeaux Society of Medicine and Surgery by Dr. Dunogier, who related a case of relapsing anginalitis caused by the eruption of the lower wisdom teeth and a case of chronic amygdalitis kept up by difficulty in the eruption of a wisdom tooth. The treatment of such cases, the author remarks, is of two sorts—preventive and curative. In regard to the practice of extracting the first molar tooth at about the eleventh year of age, he confesses that he does not share the apprehensions that have led some of his *confrères* to advocate that procedure, and he adds that he has never seen the regularity of the dental arch interfered with by allowing the tooth to remain. Moreover, he does not consider that complications due to the appearance of the wisdom teeth occur often enough to call for the extraction of the first molars as a preventive. Curative treatment, of course, consists in doing away with the cause, meaning not necessarily the tooth, unless it deviates, but the gum. In some cases the application of chromic acid has succeeded, but this agent is not to be advised in general, because, although it is undoubtedly efficacious, it acts much too slowly. The Paquelin canter and the galvanic cautery, although much easier to manage than the old actual cauteries, are not to be preferred to excision. Early in his practice the author tried excision with the bistoury and curved scissors, but the operation was very inconvenient, so that he has of late employed an instrument made specially for the purpose—a sort of *emporte-pièce*—which he showed at the meeting. After the gum has been anesthetized by means of tampons of cotton soaked in a solution of cocaine, the blade is slid under the gum covering the tooth as far as possible and the tissue divided. Gargling for a few times with antiseptics and cauterization of the neighboring ulcerated and inflamed parts with chromic acid complete the cure. Chromic acid applied to the gums

causes little or no pain, even without the previous use of an anæsthetic, and the acid has, moreover, the advantage of not in any way changing the color or structure of the teeth.

THE USE OF BORIC ACID IN TYPHOID FEVER.

The *Union médicale* for November 7th gives a *résumé* of an article by Dr. L. Tortchinsky, published in the *Gazette hebdomadaire de Bordeaux*. The author used boric acid in two hundred and forty cases of typhoid fever in the course of an epidemic, and reports excellent results; only nine patients died, and they succumbed during the period of convalescence because they got out of bed too soon or committed errors in diet. The two hundred and thirty-one other patients made a rapid and complete recovery. In all the cases the patients were given a dose of castor oil with from five to ten drops of oil of turpentine. After this mixture had operated the administration of boric acid was begun, the remedy being given internally, either in powder or in solution, in doses ranging from twelve to fifteen grains for an adult three or four times a day. When there was bronchitis the boric acid was associated with expectorants and with hydrochloric acid. As a general rule, at the end of from three to five days the fever and the diarrhoea underwent a noteworthy diminution, the tympanites disappeared, the dejecta lost their odor and became normal in appearance, the urine became abundant and in every way normal, the tongue and skin grew moist, and the general condition was good. As soon as the amelioration was well marked the use of the acid was discontinued and tonics were ordered. Under the influence of this treatment the disease followed a favorable course, its duration was somewhat diminished, and complications were very rare. The most decided effects were obtained in cases treated early. The author has found that the effects of the boric-acid treatment may be increased by combining with that drug small doses of acetanilide, quinine, naphthaline, or salol. The mixture with quinine is especially useful in the last stages of the fever, when there are ataxia, delirium, and other cerebral symptoms; it is useful also in cases of relapse. The author has never observed any harmful effect from the use of boric acid. He has also produced satisfactory results with this acid in the treatment of the summer diarrhoea of children.

BASOPHOBIA.

The *Medical Week* for November 24th states that Professor Debove reported at a recent meeting of the Hospital Medical Society of Paris a peculiar disturbance of locomotion in which there is complete loss of the power of walking or standing erect, due to emotional causes, although the strength of the muscles concerned is not appreciably diminished. A woman, aged forty-eight years, had these peculiar symptoms as the result of a violent emotion. During ten years she gradually went from bad to worse until her admission to the hospital, when she could not walk without assistance, though she could go from one end of the room to the other if somebody held her by the hand. In the recumbent posture she had no difficulty whatever in going through all the voluntary movements she was asked to perform. General and special sensibility were intact, and there was no impairment of the muscular power. The knee reflex was absent on both sides, but she presented no other symptom of tabes, and there was no evidence of hysteria. There was a certain resemblance between the symptoms observed in this patient and those of agoraphobia, from which they differed, however, in the absence of the feeling of anxiety characteristic of the latter affection. Moreover, the inability to

walk or stand erect was present as well in a closed room as in open spaces. In astasia-abasia there is an absolute impossibility of walking or assuming the erect posture, with no impairment of the muscular power or inco-ordination of movements, and it seems to indicate a loss of memory of how to walk; these patients experience no fear or anxiety on endeavoring to perform the movements of locomotion, hence no amount of encouragement or assistance will enable them to walk or stand. On the contrary, basophobias are perfectly cognizant of the fact that the difficulty they experience in assuming or maintaining the erect posture is due to a feeling of apprehension that they are unable to overcome.

RECOVERY AFTER FRACTURE OF THE BASE OF THE SKULL.

In a recent number of the *Lancet* Dr. D. L. Davies reports a case which recently came under his notice, to show that fracture of the base of the skull in elderly people does not always involve an unfavorable prognosis. The patient, a woman fifty-six years of age, was struck by a stone weighing nearly fifteen pounds, which had been dislodged from a cliff about forty feet high. The stone struck on the woman's cranium in an oblique direction at a point three inches above the base of the mastoid process of the temporal bone. A hematoma formed over the part struck, and a fracture extending downward and across the base of the skull through the petrous portion of the temporal bone was diagnosed. There was bleeding from the right ear and there was vomiting of dark blood. The patient recovered consciousness in three hours, and the vomiting ceased in about twelve hours. She had attacks of hemorrhage from the ear on several occasions during the first three weeks, and some cerebro-spinal fluid oozed for the first week. There was also oozing of blood through the orifice of the Eustachian tube. The treatment carried out was the one usually prescribed, with the exception of plugging the ear, as is often done where there is hemorrhage. The ear was syringed with a weak carbolic-acid solution, and then filled up with either boric acid or iodoform. The author is satisfied that if the ear had been plugged fatal compression would have been produced, and that in all cases it is wiser to allow the blood to escape externally. At the end of six weeks the patient was able to take a trip of two hundred miles by rail, and reported that she felt well and had no headache.

THE PREVALENCE OF TYPHOID FEVER IN DUBLIN.

TYPHOID fever always prevails more or less in Dublin, and there seems little chance of improvement until a proper main drainage scheme has been carried out. The corporation has adopted a scheme, but, singular to state, there is no provision for subsoil drainage, and typhoid fever will never be eradicated or lessened until arrangements are carried out for pumping away this water as it collects; otherwise large portions of the city are waterlogged. Sir Charles Cameron, medical officer of health for Dublin, considers that the disease, in Dublin at least, is of a miasmatic character. This year it has been more fatal than in 1892, and for the September quarter of the year seventy deaths were ascribed to the disease, against twenty-nine for the third quarter of each of the past ten years. So that, despite the various sanitary improvements that have taken place for the past ten years in house drains, scavenging, etc., and the fact that the water supply is of a pure character, yet the disease seems to increase and exists in Dublin to a much greater extent than is the case in a great majority of British and Irish towns. There seems to be a growing belief that, besides a better main

drainage and an arrangement for soil drainage, there should be a house-to-house inspection of the drains (which should be put in order when necessary) by competent sanitary engineers.

THE BACTERIOLOGY OF CHOLERA.

The *Lancet* for November 25th contains an article on the bacteriological interpretation of cholera in England. The bacteriologist, says the writer, has commonly no difficulty in affirming certain attacks of illness to have been Asiatic cholera; on the other hand, there are not a few cases which, from the bacteriological point of view, are declared to be unquestionable examples of cholera that have not always appeared to be such, judging from the clinical phenomena, the antecedent history, and the surroundings. It is in its negative aspects that the testimony of bacteriology with regard to cholera is even more unsatisfactory. Many experienced observers who have devoted exceptional attention to the clinical diagnosis of cholera have met with cases presenting clinically and pathologically all the characters of Asiatic cholera and occurring, moreover, at times when, and in localities where, true cholera was rife, but which nevertheless have afforded no evidence whatever of the presence of Koch's comma bacillus. It is facts of the latter class that tend to influence certain pathologists who, while accepting Koch's comma bacillus as an everyday concomitant of cholera, have hesitated in accepting that vibrio as the *causa causans* of the disease. Facts of an allied sort have led to considerable difficulty in distinguishing between cases of true cholera of the Asiatic type and rapidly fatal attacks of so-called English cholera. A considerable study is being made at present with reference to the exact connection which exists between Asiatic cholera and Koch's comma bacillus.

THE TREATMENT OF LOCOMOTOR ATAXIA WITH PHOSPHATIC INJECTIONS.

This method of treatment has of late been successfully used in Brussels and Geneva in advanced cases of locomotor ataxy. Dr. Forbes Winslow, in a recent communication to the *Lancet*, corroborates the reports of its efficiency and details notes of a bad case cured by injections of phosphate of sodium. The patient was seen by the late Sir Andrew Clark, who regarded the case as incurable. The injections were made in the neighborhood of the spinal column, and when twenty-five had been given marked improvement was visible, and after the fiftieth injection the patient was completely cured. Dr. Winslow states emphatically that in a certain class of cases where locomotor ataxia exists, as well as in some forms of mental disorder, absolute cures have taken place, and in cases in which the prognosis appeared grave and unfavorable. Messrs. Burroughs and Wellcome prepare tabloids which contain, we understand, ten centigrammes of the phosphate of sodium as the active ingredient.

FOOTBALL AS A FORM OF ATHLETICS.

The *Boston Medical and Surgical Journal* for November 23d concludes an editorial article on football as follows: "We have no prejudices against fencing because it comes to us from France, against golf because its home is in Scotland, nor against polo, hunting, and football because they are adopted from England. A sport which has nothing more than fashion to recommend it will not hold its own. Though football as now played really seems to us a poor game for a large number of spectators, it is, we believe, not likely soon to lose its hold upon its vota-

ries, and that because it has many intrinsic merits as a manly sport. We ourselves prefer the golf stick or the tennis racket, but we are forced to admit that we are quite beyond a certain age, and we are also willing to admit that there was a time when wallowing in the mud, even as a substitute, would not have been thought inglorious."

THE END OF AN UNCALLED-FOR ACTION AT LAW.

LAST Saturday Commissioner Fairchild, sitting in Buffalo, dismissed an action that had been brought by Mr. Anthony Comstock against a firm engaged in the manufacture of surgical tables for having sent through the mails circulars illustrating their wares by means of pictures showing nude persons in various attitudes on their tables. We are informed that these delineations are reproductions of those published in the reading-matter of different reputable medical journals, and that the circulars are sent to members of the medical profession only. That being the case, it does not seem to us that Mr. Comstock was justified in his attempt to suppress them.

NEUROTIC ENURESIS.

In the *Neurologisches Centralblatt* Dr. Freund describes a condition which he finds present in a great many cases of nocturnal incontinence of urine. It consists of hypertonicity of the lower extremities, which often exists in a very great degree without any other sign of functional disturbance. On attempting to separate the child's legs a sense of resistance is experienced, which, however, is gradually overcome, the condition appearing to be one of spasm of the adductor muscles. This symptom has been found by the author to be present in about half the cases of enuresis examined by him.

THE BRITISH MEDICAL JOURNAL.

In the issue of that journal for December 2d the editor writes charmingly of the net results of his visit to this country. He is evidently full of pleasant memories of his trip. He has made arrangements for special correspondence from New York, Philadelphia, and Chicago, as to the doings and thoughts and the best aspirations of the American profession. These, he says, are the results of the gracious invitation and most courteous and warm reception which were extended throughout the States to the representative of that journal.

THE TRI-STATE MEDICAL JOURNAL.

This is the title of a new monthly journal published in Keokuk, Iowa, and edited by Dr. James Moores Ball and Dr. George Edward Marshall, the first number of which is dated December 18, 1893. The issue consists of twenty-eight large octavo pages of reading matter arranged under the heads of original articles, of which there are five, editorials, book notices, historical and biographical sketches, and miscellany. The new journal presents a creditable appearance and is adorned with the picture of an ancient bust of Hippocrates.

THE NEW YORK STATE BOARD OF LUNACY.

THE letter signed "Physician" which we publish in this issue seems to be a fair index of the indignation felt by the medical profession at the treatment recently received by the superintendents and governing bodies of the State hospitals at the hands of the Board of Lunacy. Before commenting at greater length on the matter, however, we think it proper to

wait a while to see what justification or palliation of the board's action may come to light.

PULMONARY CONSUMPTION AND THE CITY BOARD OF HEALTH.

THE interest lately manifested by the board in measures that it is hoped will limit the prevalence of pulmonary consumption, as shown by Dr. Biggs's report published in our last issue, is most commendable. One need not pin his faith to every detail of the measures recommended in the report, for nothing but experience in their operation can settle questions pertaining to their utility and practicability. The board can, we think, be trusted in such matters, and it is to be hoped that it will be enabled to enter upon an earnest attempt to stay the ravages of tuberculosis.

THE DIURETIC PROPERTIES OF THEOBROMINE.

THE *Medical Week* for December 1st states that at a recent meeting of the Therapeutical Society of Paris, Dr. Hallopeau said that he had administered theobromine in general oedema that had resisted all other remedies. The oedema had disappeared under the influence of four doses of fifteen grains of theobromine, although the diuresis was not excessive. The result had been permanent.

ITEMS, ETC.

The Newark, N. J., German Hospital.—This institution was last week presented with an annex, to be known as the Trefz School for Trained Nurses. It is a three-story building containing in its upper portion rooms and generous accommodations for fourteen nurses. There are also training appliances and a lecture-room. The lower parts of the building will be fitted up for a general storeroom for the hospital. The annex is the gift of a wealthy German lady of Newark. The cost is estimated at \$20,000. An address was delivered by Dr. C. F. J. Lehlbach.

Tufts College Medical School.—This new venture, in Boston, is designed for both male and female students. The first year's class contains over seventy pupils. The school has temporary quarters at No. 188 Boylston Street.

St. Luke's Hospital.—Dr. Van Horne Norrie has been appointed an attending physician, to succeed Dr. George L. Peabody.

Change of Address.—Dr. Samuel W. Lambert, to No. 110 East Thirty-fifth Street.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 3 to December 9, 1893:*

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon, is granted leave of absence for four months, to take effect on or about January 4, 1894.

CLEARY, PETER J. A., Major and Surgeon. The leave of absence granted on surgeon's certificate of disability is extended four months on surgeon's certificate of disability, on condition that he report in person to the commanding officer, Army and Navy General Hospital, Hot Springs, Ark., on or before December 11, 1893, for treatment therein.

BROOKE, JOHN, Major and Surgeon, is granted leave of absence until February 22, 1894.

TEN Eyck, BENJAMIN L., First Lieutenant and Assistant Surgeon, is assigned to station at Fort McIntosh, Texas, for field duty in the Department of Texas.

By direction of the President, the retirement from active service this date, December 4, 1893, by operation of law, of PAGE, CHARLES, Colonel and Assistant Surgeon General, under the provisions of the act of Congress approved June 30, 1892, is announced.

WILCOX, CHARLES, First Lieutenant and Assistant Surgeon, will be relieved from temporary duty at Angel Island, California, on the arrival there of POPE, BENJAMIN F., Major and Surgeon, and will report in person to the commanding officer, Boise Barracks, Idaho.

WINTER, FRANCIS A., First Lieutenant and Assistant Surgeon, is relieved from further duty at Fort Wingate, New Mexico, and from temporary duty at Fort Bayard, New Mexico, and will proceed to new Fort Bliss, Texas, and report in person to the commanding officer for duty at that station.

Society Meetings for the Coming Week:

MONDAY, December 18th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, December 19th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings; Ogdensburg, N. Y., Medical Association; Baltimore Academy of Medicine.

WEDNESDAY, December 20th: New York Academy of Medicine (Section in Public Health and Hygiene); Harlem Medical Association of the City of New York; Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); Medical Societies of the Counties of Allegany (quarterly) and Tompkins (semi annual—Ithaca), N. Y.; New Jersey Academy of Medicine (Newark).

THURSDAY, December 21st: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, December 22d: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, December 23d: New York Medical and Surgical Society (private).

Answers to Correspondents:

No. 418.—The action you mention was taken by the association several years ago, but we can not tell just when.

No. 419.—Dr. F. A. Packard gives the following formula for gluten bread in his article on Diabetes Mellitus in *Hare's System of Therapeutics*: Take one quart of sweet milk or milk and water, one heaping teaspoonful of good butter, one fifth of a cake of compressed yeast beaten up with a little water, and two eggs well beaten. Stir in the gluten flour until a soft dough is formed, knead as in making ordinary bread, put into pans to rise, and, when light, bake in a hot oven.

upon the presence of tubercle bacilli in the discharges. That without tubercle bacilli there is no tuberculosis is a statement familiar to all, but with the truth or falsity of that proposition I do not propose to deal in this communication; I wish to call your readers' attention, however, to a few facts bearing upon the converse proposition—viz., that the presence of tubercle bacilli in the discharges is sufficient reason for a diagnosis of tuberculosis.

A priori, it is supposable that any patient afflicted with an inflammation of the respiratory tract may expectorate matter containing tubercle bacilli, and that these may play no rôle whatever in his case. If they are the cause of tuberculosis, a certain period must elapse between their lodgment in the air-passages and the onset of pathological changes in the tissues. Their effect upon the tissues can not be instantaneous, and during the period of incubation there is no reason to suppose that the discharges may not contain bacilli. On the other hand, there is no reason to suppose that every one who takes tubercle bacilli into his respiratory tract will be affected with tuberculosis. The discharge from such a person may contain bacilli without subsequent development of tubercular lesions.

But my object is not to theorize, but to present a few facts bearing upon this matter which have come to my attention. I have observed two cases of syphilis of the throat which are worthy of record in this relation. One of the patients gave a history of cough and expectoration, extending through two or three months, which had resisted every treatment. The cough was stridulous and the voice hoarse. There was loss of flesh and strength, and there was dyspnoea on exercise. Examination of the throat revealed marked redness and swelling of the mucous membrane of the larynx, especially over the arytenoid cartilages, and a few scattered superficial ulcerations. Examination of the chest was not satisfactory, owing to the sounds transmitted from the larynx. There was no family history of pulmonary disease. I had treated this patient on former occasions for syphilis. No history of syphilis was obtainable, but the lesions had been sufficient to warrant that diagnosis, and treatment proved the correctness of the supposition. The patient had taken iodide of potassium nearly continuously up to the time when the cough began; it was said to have started after an exposure to cold. Notwithstanding my familiarity with the patient's constitutional condition, I was not disposed, without further evidence, to look upon the present symptoms as an outbreak of syphilis. The case impressed me as possibly one of tuberculosis. Therefore I procured some of the sputum and had it examined by Dr. C. S. Boynton, of this city. He reported the presence of tubercle bacilli in it. The results of the microscopical examination were positive. After a week or ten days I saw the patient again. The principal change was an increase of the dyspnoea, which at times was alarming. I ordered at once iodide of potassium in as large doses as could be borne. The symptoms began to abate after a few days, and after a few weeks the patient had entirely recovered. More than a year later the disease had not relapsed.

A few months later I saw another patient whose history was that of cough and progressive loss of flesh and strength for some weeks, whose symptoms had not been relieved by treatment. There was an imperfect history of syphilis. Examination of the chest was negative. There was a slight difference between the two sides at the apices of the lungs; but whether this was the normal difference or not could not be determined at once. There was some thickening and superficial ulceration of the mucous membrane of the pharynx above the soft palate, also some redness of the vocal cords. For further enlightenment I had the sputum sent to Dr. C. S. Boynton for examination. He reported positively the presence in it of

Letters to the Editor.

TUBERCLE BACILLI AND THE DIAGNOSIS OF TUBERCULOSIS OF THE AIR-PASSAGES.

BURLINGTON, VT., December 5, 1893.

To the Editor of the *New York Medical Journal*:

SIR: It is well known that there exists a disposition to make the diagnosis of tuberculosis of the air-passages pivot

the bacilli of tuberculosis. The patient was, however, put on the use of iodide of potassium and bichloride of mercury, and his throat was treated with nitrate-of-silver solution. After a few weeks the symptoms abated, and he was discharged from the hospital with an injunction to take the iodide for several months and to return if he experienced a relapse. I have not seen him since, and it is now more than a year.

Both these patients would have perished had the diagnosis suggested by the microscope's revelations been justifiable.

It may be objected that Dr. Boynton was in error when he reported the presence of tubercle bacilli in those specimens. If so, it was an error committed by a man competent to make such examinations, and the objection is one that would shake my faith in the revelations of the instrument at the hands of any observer.

I am aware that this subject is an old one, but it has seemed to me not altogether unprofitable to consume your readers' time in this way for a brief minute.

J. H. WOODWARD, M. D.

THE NEW YORK STATE COMMISSION IN LUNACY AND THE STATE HOSPITALS.

YONKERS, N. Y., December 11, 1893.

To the Editor of the New York Medical Journal:

SIR: Inclosed herewith will be found a few clippings from various newspapers published in this State containing editorial and other references to the pending controversy between the State Commission in Lunacy and the officers of the State hospitals.

One is amazed to find from the statement of the trustees of the Utica State Hospital that two members of the lunacy commission personally requested the superintendent of that institution to send to the commission estimates for certain things which, when received, were promptly disallowed. More than this, these same commissioners, one of whom is a physician, a former superintendent of a State hospital, a member of the American Medico-psychological Society (the successor of the Association of Medical Superintendents of American Institutions for the Insane), and a member of the New York State Medical Society, proceeded to state in a newspaper interview that by cutting off these and other items they had effected a great saving to the State!

No wonder that trustees and superintendents protest. It would be interesting to know upon what interpretation of the code of medical ethics the chairman of the lunacy commission officially requests a medical superintendent, a member of his own societies, to place items upon an estimate apparently for the express purpose of creating an opportunity to prefer, at least by implication, charges of extravagance and wastefulness against that superintendent, and then to draw attention through the newspapers to his own superior penetration, wisdom, and probity in detecting such extravagance and in so promptly checking it. Whatever else may be the merits of this controversy, it is perfectly evident to all respectable and self-respecting medical men that the superintendents of the State hospitals are entitled to the fullest support in their demand to be treated as gentlemen. Unhappily the position in which two at least of the commissioners in lunacy have been placed by their own utterances, and the reply thereto by the trustees of the Utica State Hospital, is not such as would be willingly assumed by any gentleman of my acquaintance, and indeed would almost make it appear as though the chairman himself were wanting in that nice sense of professional courtesy,

and dignity, and honor the possession and practice of which no physician has ever heretofore suspected to be incompatible with personal or official integrity and efficiency. PHYSICIAN.

Book Notices.

The Medical Student's Manual of Chemistry. By R. A. WITTHAUS, A. M., M. D., Professor of Chemistry and Physics in the University of the City of New York, etc. Fourth Edition. New York: William Wood & Co., 1893. Pp. xiii-543. [Price, \$3.75.]

THAT the fourth edition of this standard work has fifteen more pages than the third, published only three years ago, is not the sole indication of the additions that the author has made. Throughout the volume, especially in the chemistry of organic substances, there are changes that embody the latest discoveries in chemistry.

The present edition is deserving of the commendation bestowed upon its predecessors, and sustains the excellent reputation the work enjoys.

A Laboratory Guide in Urinalysis [sic] and Toxicology. By R. A. WITTHAUS, A. M., M. D., Professor of Chemistry and Physics in the Medical Department, University of the City of New York. Third Edition. New York: William Wood & Co., 1893. Pp. vi-99. [Price, \$1.]

THE author has taken the opportunity of the preparation of a third edition of his useful guide in urinalysis to introduce some new directions for qualitative analysis and to insist that all examinations of this character should be made with samples of the mixed urine of twenty-four hours. The directions for determining the constituents of the urine are given with the clearness and brevity characteristic of the former editions. If in a work of this character it is deemed necessary to give the antidotes for any of the toxic agents, we do not see why the author has omitted reference to the hypodermic injection of apomorphine wherever he has mentioned the stomach pump.

This little book will be found as useful to the practitioner in his daily work as to the student in the laboratory. The book, indeed, is better than its title. Properly, there is no such word as "urinalysis"; it should be *uranalysis*.

Chemistry and Physics. A Manual for Students and Practitioners. By JOSEPH STRUTHERS, Ph. B., Columbia College School of Mines, New York; D. W. WARD, Ph. B., Columbia College School of Mines, New York; and CHARLES H. WILLMARTH, M. S., New York. Series edited by BERN B. GALLAUDET, M. D., Demonstrator of Anatomy, College of Physicians and Surgeons, New York. Philadelphia: Lea Brothers & Co., 1893. Pp. vii-17 to 288. [*The Students' Quiz Series.*]

THIS volume is intended to serve as an auxiliary to the lectures the student hears and as a review work for teachers. The greater portion of the volume is devoted to chemistry, so that the part devoted to physics is meager. There is no reference to Montgolfier's theorem that is necessary to determine the rate of movement of air through a ventilating aperture, or to Mariotte's law, or to several other laws of physics that are likely to prove useful to the medical student.

BOOKS, ETC., RECEIVED.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M. D., F. R. C. P., F. R. S., Consulting Physician to University College Hospital, etc. Second Edition, revised and enlarged. Vol. II, Diseases of the Brain and Cranial Nerves; General and Functional Diseases of the Nervous System. With One Hundred and Eighty-two Illustrations, including a large number of figures. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xvi+1069. [Price, \$4.50.]

Miscellany.

The Relation of General Disease to the Formation of

Cataract.—At a recent meeting of the Philadelphia County Medical Society Dr. G. E. de Schweinitz read a paper in which he said that the etiology of cataract was by no means always clear, and, independently of the studies which pertained to the pathological anatomy of opacity of the crystalline lens, much interest attached to the causes which might originate the clouding of its structure. He entirely omitted reference to the influence of age, sex, occupation, heredity, diseases of the eye, and accommodative strain, each and all of which were important factors, and desired to call attention to those cases which bore some relation to nutritive disturbances, which in their turn were dependent upon constitutional disease, or upon more localized extra-ocular conditions. It was evident that trustworthy information on this point could be obtained, had it been the custom of general practitioners to make as careful an examination of the transparent media and fundus of the eye as they did of other organs, in the study of the symptomatology of the cases of general disease which had come under their care. In the absence of such systematic examinations, ophthalmic surgeons were forced to gather the evidence, except in a few instances, from reports scattered here and there through the literature, many of which were valueless, inasmuch as they proved nothing more than probable coincidence. Therefore this topic had been introduced for the consideration of a general medical society, in the hope that it might stimulate research in this line. Doubtless useful data could be gathered were general practitioners and ophthalmologists—serving at the same time in large hospitals—to combine their efforts in the study of each case of constitutional disease from its beginning to its close. How much reliable information would thereby be added to the already large store of knowledge belonging to medical ophthalmology could only be imagined.

For convenience of study, he had arranged the cases in which this disease bore some relation to the formation of cataract into—

I. IDIOPATHIC FEVERS AND ALLIED DISEASES. (a) *Typhus and Typhoid Fever*.—It was a matter of common observation that the clinical history of cataract formation would not infrequently reveal that the patient referred marked failure of sight to some decided febrile disturbance, but it was difficult to prove that this had positively been the cause of the depreciation in vision. For example, Galezowski* had investigated 4,776 cataracts with reference to their etiology, and had attributed by far the greatest number—1,538—to age, as they had occurred between the sixtieth and the seventieth years. Therefore the majority had been representatives of a retrograde process in a changing organism. The remainder, exclusive of those which had occurred under the influence of injury and heredity, had been ascribed to excesses, accommodative strain, and finally to debility of the

* De l'étiologie de la cataracte. *Recueil d'ophth.*, 1883, p. 17.

body as the result of constitutional and febrile illnesses—that is to say, this debility had hastened the cataractous process.

A little more to the point, but none the less of indifferent value, were the observations by Trelat* on cataracts following typhoid fever, in which he described double, semisoft cataracts in a young girl which had begun to develop during convalescence from typhoid fever. Arenst† had examined two young people, brother and sister, who had developed double cataract, which had become total in one eye, after an attack of typhus fever. A good result after extraction had been secured. Fontan‡ reported three cases of post-typhoid cataract (cataracta punctata) which he believed had been the result of mechanical obstruction of the circulation. In two of the patients—one a man twenty-eight years old, and the other a woman forty-two years old—the cataract had progressed to maturity and had required extraction. There was no evidence from this paper, however, that Fontan had been aware of the condition of the transparent media before the typhoid attack.

(b) *The Exanthemata*.—As the malnutrition of typhus and typhoid fever might perhaps be responsible for lenticular opacities, also this was true of the various exanthemata, quite independently of the fact that these diseases might cause local inflammatory conditions which would determine the opacification. Romiëe,§ for example, had analyzed forty four cases of cataracta punctata, and had attributed the pathogenic cause to typhoid fever seventeen times, variola seven times, and scarlet fever three times. Chlorosis had been made responsible seven times, and the remaining ten instances had been ascribed to diverse maladies—suppuration, heart disease, rachitis, etc. The author sought to explain the lenticular opacities by an increase in the density of the serum and changes in the relation of the lens to the aqueous humor.

(c) *Whooping-cough*.—For the most part, the reports concerning the relation between whooping-cough and cataract formation were vague—for example, such indefinite cases as had been reported in pre-ophthalmoscopic days by Wright|| who recorded the case of a baby, aged eighteen months, who had been able to see for twelve months, then had had whooping-cough, and afterward cataract.

(d) *Malaria*.—Inasmuch as severe malarial fever of any type might be accompanied by lesions in the vitreous and the choroid—for example, hemorrhage, which after absorption left membranous opacities and areas of atrophic chorioiditis—there was no reason why cataract should not form. A more direct connection than this seemed doubtful. Bagot,^ however, described two cases in mulattoes who, directly at the close of a violent malarial illness, had suffered from diminution of visual acuity, and a few months later double soft cataract had been evident. After operative interference the visual acuity had returned to normal, and there had been no lesions in the fundus oculi.

(e) *Epidemic Influenza*.—During the prevalence of epidemic influenza, or *la grippe*, so fresh in the minds of all of us, a large amount of attention had been directed to the ocular lesions, and a great variety of affections, inflammatory and otherwise, which had occurred in the eyes of the sufferers had been attributed, and no doubt in many instances rightly, to the influence of this extraordinary disease. It would be out of place to attempt a review of the literature, which was very considerable

but, as an example of what had been observed, he would quote a single analysis—namely, that of Rampoldi.* Among five hundred and thirty-two eye patients whom he had seen during the months of February and March, 1890, there had been forty-eight who had acquired their ocular trouble during or after an attack of influenza. These affections had been acute conjunctivitis, conjunctival abscess, abrasion of the corneal epithelium, corneal infiltrations, corneal abscess, iridocyclitis, serpent ulcer, serous iritis, chorioiditis, detachment of the retina, and affections pertaining to the external and internal ocular muscles. Therefore it was not unlikely that this disease, producing such serious inflammatory lesions, might be followed by cataract, and this probably was the explanation of such cases as had been reported.

One case out of several which had occurred in his practice might be quoted: A private patient, a woman, aged fifty-five years, had applied for treatment on the 25th of July, 1891. She had been in good health except during the winters of 1890 and 1891, when she had had sharp attacks of *la grippe*. Following these, vision had begun to fail, associated with a dull, aching pain in the eyes. In the right eye there had been large striae in the lens down and in; the optic disc a vertical oval, of good color, but with undue broadening of the scleral ring. In the left eye there had been larger punctate opacities in the posterior cortical and also in the vitreous. No hemorrhages had occurred in the eye grounds. Previous to these attacks of *la grippe* the media had been clear. It was very evident that one of the common lesions of influenza had been present in this patient—namely, vitreous disease, which in its turn had been no doubt responsible for the formation of cataract that had since gone on to maturity in the left eye.

II. CONSTITUTIONAL DISEASES. (a) *Gout*.—This ubiquitous disease had been made responsible for a great variety of ocular affections, and, naturally, cataract had not escaped. Zychon† contributed an article upon the influence of gout in ophthalmic disorders. Michel, who abstracted the article in the *Jahresbericht f. Ophthalmologie*, vol. xvi, p. 318, somewhat sarcastically stated: "We know from Zychon's teacher, Galezewski, that gout has been made responsible for all possible and impossible eye diseases, and so we are not surprised when to the list of gouty ocular affections the following are added: Lithiasis of the lids, dry eczema, subconjunctival ecchymosis, conjunctivitis, calcareous degeneration of Bowman's membrane, scleritis and iritis, chorioiditis and cyclitis, retinitis and chorioido retinitis, cataract, glaucoma, arterial thromboses, muscular pelsies, and, finally, migraine." Now, in spite of Michel's unnecessary criticism of this author, many of these affections were undoubtedly gouty, and because the uveal tract fell under its baleful influence, cataract might be indirectly caused by this disease, but not, however, without the intervention of inflammatory lesions, which attacked those portions of the eye particularly concerned in the nutrition of the crystalline lens.

(b) *Rachitis*.—Punctate cataract—if the report of Romiëe‡ might be credited—sometimes occurred in connection with rachitis, and Nicati* brought the total number of cataracts (not congenital) which were sometimes found in children into ætiological relationship with rachitis.

One form of cataract, variously called zonular or lamellar, which anatomically consisted of a narrow zone of degenerative change in the lens fibers situated between the nuclear and cor-

tial areas, had often been attributed to rachitis. The true cause, however, was not certainly known. The congenital variety was probably due to some developmental defect; in the form arising in early infancy some fault in nutrition had occurred; most frequently the subjects were rachitic and presented the teeth and cranial asymmetry peculiar to this affection. A history of convulsions was common, and the dental defects which were present in the form of lines, furrows, or terraces, running transversely across the incisors or canines, were considered by Hutchinson to be due to the mercury which in all probability had been given for the convulsions, which in their turn had caused the cataract. Therefore the cause did not reside in rachitis itself, but in the frequent, severe, and long-continued convulsions to which its subjects were liable. Moreover, as Knies,* quoting Arlt, pointed out, the cause did not pertain alone to the general convulsions, but to the disturbance of the lens brought about by the severe ciliary muscle cramp which was said to be present in all universal convulsive affections. Such a result could obtain, however, only in the earlier years of life, while the process of development in the lens was still an active one.

(c) *Constitutional Syphilis*.—This disease, like other affections which were prone to attack the uveal tract, was not infrequently followed by secondary cataract as the result of disturbances in the nutritive processes of the eye. Some authors, however, had described so-called true syphilitic cataract. For example, Bos† recorded several examples from Badal's clinic, and referred to others which had been seen by Heller‡ and Romée.* He divided these cases into two classes: 1. Capsular cataracts which were associated with iritis, etc. 2. Lenticular or true cataracts, which were rare and directly due to syphilis. They were soft and appeared in the second period of this disease, presumably without the intervention of inflammatory processes in the ocular coats.

(d) *Diabetes*.—The usual answer to the question, "What is the most frequent ocular lesion in diabetes?" was "cataract." Ever since the observations of France,|| in England, and the still earlier ones of Mackenzie and Duncan, as well as those of von Graefe, up to the present time, an enormous amount of literature had accumulated with reference to the relation of saccharine diabetes to the formation of cataract, and to its influence upon operative interference in this disease. It had become the rule to examine the urine carefully for sugar in all cases of cataract, especially when it developed in young subjects, and it was well known that in fully one per cent. of the cases sugar would be detected, and, moreover, that the cataractous lenses of patients who were the subjects of diabetes mellitus occasionally contained sugar. From the experimental standpoint, especially the researches of Mitchell and Deutschmann, it was known that the injection of large quantities of salt or syrup into the tissues of the lower animals might cause opacity of the lens, the result probably of the extraction of water from the lens and interference with its nutrition. We also had in evidence the occasional spontaneous disappearance of diabetic cataract, in some instances corresponding with a diminution of the amount of sugar in the urine. Knies thus summarized the various theories which had been brought forward to explain the connection between diabetes and cataract.

* *Loc. cit.*

|| *Guy's Hospital Reports*, 1859, vol. i, p. 273.

It might result from: 1. A general marasmus. The objection to this hypothesis was that in very high grades of depraved nutrition occurring in diabetes quite frequently there was no cataract. 2. The abstraction of water from the lens by means of the sugar in the tissues, which, in fact, very frequently, if not as a rule, was found in the lens, and more often in the aqueous humor and in the vitreous. If this had been true, however, after a time all diabetics would suffer from cataract, which was not the case. Besides, as Leber had shown, both the opaque and the clear lens might contain sugar in diabetic patients, and Becker had described cases in which, in one eye, the cataractous lens had contained sugar and in the other it had not. 3. Finally, there was the theory that the sugar contained in the aqueous chamber underwent a change into lactic acid, which in its turn caused the cataract. This theory had no foundation, inasmuch as the aqueous humor was alkaline, even though there was diabetic cataract, and, in the second place, the opacity did not begin in the anterior cortical portions of the lens.

Tonching the pathology of this affection, and throwing some light upon the relationship between the disorders, Deutschmann* had examined four patients with diabetic cataract, finding proliferation of the layer of pigment cells on the posterior surface of the iris, a condition which had previously been described by Becker. In the lens there had been vesicular cells (*Blasenzellen*) and all the changes from normal uvea to complete nuclear disintegration. Deutschmann concluded that the opacity in the lens was due to a necrotic tendency of the epithelial structures, just as the same tendency was shown by all epithelial tissues in this disease. If the epithelium was normal no pathological process of diffusion took place, no matter if both vitreous and aqueous contained sugar, but when necrosis of the lenticular cells occurred abnormal diffusion currents were set up and produced opacity. Referring to these researches, and others like them, Knies pointed out that in certain cases the iris was more or less changed—sometimes atrophic, sometimes slightly inflamed—in other words, uveal-tract inflammations might be present in diabetes. The development of cataract, then, belonged not so much to the presence of sugar, but was an intoxication symptom—a species of self infection.

The relationship between diabetes and the formation of cataract, which had been accepted for many years, had recently been questioned in a publication of Mauthner's† His study included a large number of cases seen in Carlsbad. An editorial published in the *Medical News* for March 18, 1893, reviewed this paper, and from it the author extracted the following quotation as pertinent to the subject: "In most of the patients in which defects of vision were found, these could be as readily attributed to concomitant conditions, such as age, impaired nutrition, and other intrinsic influences. The number of cases of diabetes mellitus in which cataract exists will, at best, be found to be exceedingly small. It is pointed out that the peripheral striation of the lens sometimes found in diabetes, and especially in the inferior median quadrant, is quite common, and becomes progressively more frequent in individuals that have passed the fiftieth year of life. Among the influences that might be considered as favorable to the development of cataract are: The displacement of water in the fluids and tissues of the body by the presence of sugar; a diminution in the resistance of the walls of the blood-vessels as a result of the disturbances of the general nutrition; the development, as a result of the pathological me-

* *Archiv*, xxxiii, Abth. 2, p. 229.

tabolism, of toxic substances that give rise to inflammation and degeneration; the marked marasmus; complicating or intercurrent affections. If the ocular changes were due to the loss of water, they should likewise occur in simple polyuria. It is more than doubtful that opacities of the lens result from the presence of sugar, for there is evidence that the lens normally contains sugar. The development of cataract in an elderly person whose urine contains sugar does not constitute sufficient ground on which to make glycosuria responsible for the loss of transparency of the lens, for it is known that in the large majority of cases of senile cataract the urine does not contain sugar. The conclusion is reached that the presence of sugar in the fluids of the eye does not lead to any disease of the organ of vision, and especially not to the development of cataract. In a small percentage of cases of diabetes mellitus, however, the excessive elimination of sugar and of water does lead to the development of cataract."

III. LOCAL DISEASES. (a) *Diseases of the Heart and Atheroma of the Vessels*.—From time to time diseases of the heart and of the blood-vessels had been brought forward to explain the existence of cataract. One of the earliest communications on this subject was a report, by Fournieux Jordan,* on the relation of cataract to heart disease. Nineteen cases were reported: Two patients had been under twenty years of age, seven between forty and fifty, five between sixty and seventy, and five past the seventieth year. These patients had suffered from various forms of organic cardiac lesion and had had cataract. Other than this, no relationship had been demonstrated; but, as would be noticed, the majority of the cases had been at that time of life when cataract was likely to occur in the absence of constitutional disorder. The cases, however, were quoted for the reason that it had been an attempt to gain some information in regard to the ætiology of cataract, and, as had been observed in other cases, there was an occasional relationship indicating that vascular disturbances were in some way responsible for opacification in the lens. Romée (*loc. cit.*) ascribed several cases of cataracta punctata to heart disease.

A more modern view of a somewhat analogous relationship was the theory of Michel, that circulatory disturbances, and particularly atheroma of the carotid, might be responsible for the formation of cataract. Michel† had come to the conclusion that opacity in the lens substance had been a symptom of a local or general disturbance, and that so-called senile cataract had depended upon sclerotic changes in the walls of the carotid. He had analyzed fifty-three cases; in fourteen patients there had been monocular cataract, with atheroma of the carotid on the same side; in fourteen there had been double cataract which had been more developed and had begun earlier on the side of the greater atheroma; in nine cases of double cataract these had developed simultaneously with a double carotid atheroma; and in eight cases of cataract there had been sclerotic change in the carotid, and on the same side the presence of a swelling in the thyroid gland or goitre.

Other observations on the same subject had been brought forward—for example, in the thesis of Karwat,‡ which added a series of cases confirming those already reported by Michel—

‡ *Beiträge zur Erkrankung des Auges bei Karotisatherom*. Inaug. Diss., Würzburg, 1883.

namely, that there was a relationship between atheroma of the carotid and the formation of cataract.

On the other hand, Becker,* with the help of Adolf Weil, had examined fifty-three cataract patients, among whom disease of the carotid had been evident in only sixteen; in the other thirty-seven it had not been present. Among the sixteen had been six persons with atheroma more developed on the side of the lens first affected, and in the remaining ten this had not been the sequence of events. Moreover, this had been found only in individuals who had passed the fortieth year. In all four cases of one-sided cataract the condition of the circulation in general, and especially of the carotid, had been normal.

(b) *Nephritis*.—Naturally, the various types of so-called Bright's disease, and the widespread lesions which they might produce throughout the body, had been brought into connection with the formation of cataract. Deutschmann,† after reporting twenty-one cases of lenticular opacity in which he had found albumin seven times, and six times established the presence of nephritis, had called attention to the possibility of a connection between the two diseases. Still later, in 1881, the same observer‡ had found among fifty-three cataract patients 9.5 per cent. cases of Bright's disease, and again referred to the relationship between albuminuria and the development of lenticular opacities, quoting Becker, who had in a communication disputed his conclusions, and yet had found from two to eighteen per cent. of the patients suffering from albuminuria. In still a later communication Deutschmann* reported the examination of two hundred and thirty patients with uncomplicated cataract, among whom five per cent. had been undoubtedly nephritic and 11.1 per cent. probably affected with Bright's disease.

This communication had been followed by one from the pen of Landesberg,|| who described the examination of three hundred and seventy-six patients with uncomplicated lenticular opacity, finding sugar alone in the urine of three of them, sugar and albumin in two, and albumin in forty-four—therefore three hundred and twenty-seven with normal urinary analysis and forty-nine abnormal—and concluded very properly that albumin and cataract might be associated as a coincidence, but that the presence of albumin did not necessarily mean the existence of Bright's disease.

In 1886 Rothziegel^ had found albumin in more than half of his patients, and attributed this large percentage to the fact that he had examined them at many intervals during the day. He described fifteen cases of chronic nephritis with cataract, and commented upon the arterial lesions which might be present, and particularly atheroma of the carotid.

Finally, the author referred to the researches in 1887 of Eretzky,¶ who, desiring to investigate the trustworthiness of Deutschmann's albuminuria theory, had divided his methods into three portions: 1. He had examined two hundred cataract patients for albumin. Of these, thirty-five had been under fifty and one hundred and sixty-five over fifty. In thirty-eight he had found albumin—that is, in nineteen per cent. of the cases. In sixteen patients the albumin had been a constant feature, and in nine per cent. there had been albumin and tube casts, and these usually in patients under fifty years of age. 2. He had examined ninety-seven patients with chronic nephritis,

seventy under fifty and twenty-seven older, and had found the following eye complications: Albuminuric retinitis, cataract, posterior synechia, opacities in the vitreous, detached retina, and synchysis scintillans. Cataract, always incipient, had been found in eight patients, or 8.2 per cent., and one of these had an anterior polar cataract which had existed for many years, while seven of the cases had been in old people. 3. He had examined five hundred and eighty-four old people with the ophthalmoscope, and had found two hundred and four, or 45.2 per cent., with cataracts, usually incipient. Of these, there had been 20.9 per cent. in the sixth decade, 43.75 per cent. in the seventh decade, 52.6 in the eighth decade, and 66.6 per cent. in the ninth decade. Their urine had been examined, and in fifty-nine patients, or 10.5 per cent., albumin had been found, and in 1.6 per cent. tube casts. Of the cataract cases, 10.5 per cent. showed albumin; of the non-cataractous cases, 9.8 per cent. True nephritis had been found among the cataractous patients in 0.8 per cent. of the cases, and in 2.1 per cent. of the non-cataractous patients. Therefore he concluded that albumin did not mean nephritis; that nephritis and cataract might combine; that in young nephritics there was no cataract, and in old ones usually not more than in those who were without the signs of Bright's disease.

Thus it would be seen that while it was of the utmost importance, both in determining the prognosis of the affection and also that of operative interference, to examine the urine of every cataract patient, and while albumin and sometimes tube casts might be found, no causal relation had been positively established between nephritis and cataract.

(c) *Nervous Diseases*.—We had already determined that zonular cataract, which had been found in association with rhachitis, was more likely due to convulsions, or to local cramp in the ciliary muscle, than to the disease itself. In like manner, those examples which had been found in connection with other complaints, more particularly belonging to lesions of the nervous system—for example, epilepsy—were explainable by the presence of convulsive disturbances. Thus Logetschnikow* described fifteen patients between the ages of sixteen and thirty-seven who had suffered from general clonic convulsions and had developed total cataract. Their vision had been good, with the exception of one patient, before these nervous phenomena had manifested themselves. He discussed the possibilities of other causes for cataract and practically eliminated them, and concluded that the development of cataract was in relationship not alone with the convulsive seizures, but with the nervous lesion which was the basis of the convulsive efforts.

Meningitis had been made responsible for the formation of cataract in young individuals. Bock† had reported five patients, between the ages of thirty-four and thirty-nine, who had suffered from cataract, had undergone an operation, and had secured good vision. He had excluded other causes of lenticular opacity except the likelihood that the disease had followed the meningitis from which they had suffered. Examination of the eye grounds seemed to show that two might have had optic neuritis, but none the less they had done well after operation. There had been no convulsions.

Sewill‡ reported an interesting case of a patient with orbicularis spasm on the right side of the face and the development of cataract. The spasm had been caused by a carious tooth, and had ceased on its removal. He referred to trophic changes in connection with the trigeminal ganglion as a possible explanation of these phenomena.

(d) *Diseases of the Skin*.—Mooren, quoted by Norris, asserted that chronic skin eruptions might favor the development of cataract by causing creeping inflammatory processes within the eye, and Förster believed that it was not impossible that chronic skin affections might favor the development of a depraved nutrition, which in its turn produced cataract by alterations in the nutrition of the lens.

Rothmund* described an unnamed exanthem, the pathological anatomy of which had been a chronic parenchymatous inflammation of the skin, the papillary layer and rete Malpighii having been chiefly affected, which had appeared in a number of children and had been associated with the development of lenticular opacity. This had begun between the fourth and sixth years, although the skin affection had been manifested between the fourth and sixth months. The cataract had commenced in stripes, but had quickly developed and had become complete in several days. This skin affection had been compared with vitiligo, keloid, and ichthyosis, but had had sufficient individual peculiarities to separate it from each of them. No good explanation had been given of the cause of the opacity, except, perhaps, that the chronic parenchymatous inflammation of the skin had been associated with an analogous condition of the lens.

Nieden† had described the case of a girl, aged twenty two years, who had developed cataract rapidly, the opacity having been preceded by a teleangiectatic swelling of the capillaries of the face. Referring to the well-known relation of diseases of the uveal tract to the development of cataract, and to the relation of atheroma to its production, he thought the dilated capillaries might have been an indication of a vascular disturbance within the cranial cavity which had been responsible for the passage of the lens into opacity.

IV. *TOXÆMIAS*.—Although, perhaps, not belonging strictly to the list which the author had discussed, it would seem proper, in closing, to refer to one or two forms of cataract which had developed, if not under the influence of, at least in association with, the action of certain drugs. Foremost among these were the observations which related to the development of opacity of the crystalline lens in connection with ergotism, or, as it was often called, the formation of raphanic cataract.

Thus Meier‡ described twenty-three cases of ergotism—fifteen women and eight men. Their ages had been between ten and sixty, the poisoning had lasted from six weeks to three months, and the chief symptoms had been cramps and convulsions. He attributed the disease either to the action of ergot on the ciliary nerves, or to the convulsive disorder. Numerous papers had appeared upon this subject, to which further reference was unnecessary, except to say that, for example, in those cases reported by Tepljaschin,§ twenty seven in number, occurring during an epidemic of ergotism, and the patients had been, for the most part, under thirty years of age, the development of the cataract had been ascribed rather to the convulsive disorder than to any distinct action of the poison itself. Hence it seemed proved that the lenticular opacity resulted from the violent, general convulsions and not directly from the ergot.

Among other toxic agents that were known to cause cataract was naphthalin. Experimentally, cataract had been produced with this drug by feeding it to rabbits, but it should be mentioned that, in addition to the lenticular opacity, there were general disturbances as well as changes in the retina and vitreous. Other drugs and toxic agents had in a vague way

been suggested as a possible cause of opacities in the crystalline lens, but it was likely that these relationships had existed in the minds of the patients rather than in reality, and, before they could be accepted, direct experimentation, especially upon the lower animals, would be required.

Naturally the possible relationship between cataract and general disease had often been discussed, but, as might be seen from the cases quoted, the conclusion reached by Becker,* that a connecting link between constitutional maladies and opacity of the crystalline lens had not been established, remained in a large measure unshaken. To quote again from this author, said Dr. de Schweinitz: "The influence of the constitutional condition of the organism expresses itself relative to the lens, either that another portion of both eyes first becomes diseased and the pathological changes brought about in the vitreous through this means lead to the formation of cataract, or that the lymph of the body experiences changes, through which, without the evident intervention of other ocular lesions, lenticular opacity develops." None the less, as pointed out in the beginning of the paper, systematic examination of cases of general disease, especially frequent investigation of the transparent media, might throw further light upon the subject, and was a research worthy of followers.

The evident influence of eye-strain and asthenopia in its widest sense, together with the changes which this produced in the ocular coats, particularly the chorioid, referred to by Galezowski, insisted upon by Schoen, and more recently elaborated by Risley, on the formation of cataract was well established. Possibly constitutional diseases permitted this influence to be more strongly felt, and thus indirectly aided in the development of lenticular opacities, or perhaps a more direct influence could be established. Be this as it might, further critical evidence was needed.

At the same meeting Dr. Edward Jackson read a paper in which he said that the possible causes of cataract might be considered under three heads—namely, senile degeneration, disease of the eye itself, and general disease impairing the nutrition of the crystalline lens by some influence exerted through the blood or through the nervous system.

The influence of senile change was obviously indicated by the occurrence of cataract chiefly after middle life. That such an influence existed, and was powerful, probably no one questioned; but the view that it was the sole cause, or anything more than a predisposing cause in a majority of cases, seemed to be negated by the clinical history of cataract. The changes of age, those which resulted from the lapse of time and the purely physiological use of an organ under physiological conditions, must have been in the main slowly and steadily progressive; at least, if they had been more evident at some times than others, they would never have become entirely stationary or in any case retrogressive.

The one fact, however, in the clinical history of so-called senile cataract that seemed firmly established by the studies that had heretofore been made of it, was that in the majority of patients the condition was not steadily progressive, but was marked by periods of rapid increase and periods of little or no change, or even, in certain conditions, by periods of diminution of opacity.

The author remembered well a case occurring some years ago in the service of Dr. Harlan at Wills Eye Hospital, where they had been inclined to think from the appearance of the opacity that probably it would become rapidly progressive. The patient received the opinion with perfect composure and apparent indifference, the cause of which became evident when

she informed them that she had been told the same thing six years before, and that there had been no perceptible change in her vision during that interval.

In a classical case reported in the *Royal London Ophthalmic Hospital Reports*, 1866, Bowman had seen the patient eighteen years before, and had made a drawing of the opacity which substantially represented its appearance after this long interval.

In a large proportion of the cases of advanced cataract that had come to us, the history as obtained from the patient showed one or more periods of a rapid increase of the cloud over the sight, with other periods in which there had been little or no change. In his experience it was quite the exception to find that the difficulty had increased steadily and continuously after a period of months or years. From this observation the obvious deduction appeared to be that, although senility might be a predisposing cause, the efficient determining cause of cataract must have been of quite a different character, at least for the great majority of cases.

Of the importance of local pathological conditions within the eyeball, particularly those of the nutritive coat, the chorioid, the importance of which had been strongly urged by Dr. S. D. Risley, he did not propose to speak. Their importance was certainly very great, but it seemed clear to him that general conditions of nutrition were also of importance in this connection. It might be claimed that general conditions acted by their influence on the chorioid. But even admitting this, such influence often did not become evident by any changes that could be detected in that membrane, but only by the resulting altered nutrition of the lens; and the changes in the chorioid, though they might exist, being secondary to the general departure from health, the practical thing to do was to fix our attention and address our remedies to that.

The literature of cataract as carefully reviewed by Dr. de Schweinitz showed a large number of attempts to connect the occurrence of lens opacity with particular general diseases, but with conclusions based upon very insufficient data. For instance, one writer reported a series of cases of cataract in which heart disease had been present, and upon the frequency of such a concurrence attempted to establish a connection. So many were the factors to be considered that probably no statistics of concurrence possible, up to the present time, or likely to be obtainable in the near future, would furnish a substantial basis for any valuable conclusion in this direction.

Again, very many reported cases, and this applied particularly to the striking ones that might be regarded as of great value, were vitiated by probable inaccuracy of diagnosis.

The difficulty of avoiding errors of this sort might be illustrated by a case reported by Dr. Ruschenberger, of Philadelphia, in the *American Journal of the Medical Sciences* for January, 1846. In this case, which had been one of acute pneumonia, he noted that "a cataract had formed in the right eye within thirty-six hours, and without any appearance of local inflammation. It had been ashy white, and vision totally extinct." The case, however, had proved fatal. At the autopsy it had been discovered that "what had been supposed to be a cataract had proved an effusion of lymph within the margin of the pupil slightly adherent to the iris. This lymph had formed a disc, covering the anterior face of the lens, which had been transparent."

Indeed, so imperfect had been the observation of cases and the sifting of evidence bearing upon this subject, that, with regard to the share of particular diseases in the causation of cataract, it was only perhaps with reference to diabetes and ergotism that the testimony could be regarded as sufficient to establish a connection.

* *Loc. cit.*

Of course, so many inconclusive attempts to establish such a connection between cataract and disease were of value as negative evidence that no such connection existed. They did not, however, militate against the view that certain vices of general nutrition which might arise in many specific diseases were an important factor in the production of cataract.

Organic heart disease, gout, and arterial sclerosis as distinct diseases might have little connection with cataract, yet in their course there might arise the physical conditions which would in particular patients determine the opacification of the lens. To determine whether that was or was not the case would only be possible by the careful and prolonged study of individual cases, the opportunity for which was rarely accorded to the ophthalmic surgeon.

Several years ago, while in general practice, he had had an opportunity of watching a case of mitral disease, during several months of cardiac insufficiency, along with serious gastric disturbances. During this period there had been rather rapid impairment of vision through the development of lens opacity, presenting the ordinary clinical characters of cortical senile cataract. Finally, compensatory hypertrophy re-establishing the balance of the circulation, the digestive disorders had been relieved and a better state of health had been brought about. Vision had slightly improved, and for two years the cataract had remained quite stationary. After that, he was informed, the patient's impairment of vision had been very slightly progressive for several years. But prior to her death, as her general condition had become impaired, the cataract had again grown rapidly worse.

Though cases of this kind might occur frequently in such patients consulting one or more ophthalmic surgeons in the period of comparative health, they would be quite unable to establish any connection between the lens opacity and the general disease. Again, the medical practitioner who did not employ the ophthalmoscope, or who had not been sufficiently familiar with its use to exclude changes in the chorioid or vitreous from any share in the progressive impairment of vision, would be quite unable to give convincing evidence upon the subject.

It would seem that here, as in so many other cases, scientific knowledge was only to be advanced by the working together of the specialist and the general practitioner. It might be supposed that this could be accomplished in the general hospitals that had upon their staffs skilled ophthalmologists. But such a study to be of any considerable value must extend over a long period—many months or years; and hospital patients were proverbially inconstant, so that to follow them for the necessary length of time was generally quite impossible. The conditions of private practice, where the family physician remained the trusted medical adviser for years, were those most favorable to such a study, and under its conditions it ought to be more frequently undertaken.

This was especially the case, since the good of the patient urgently demanded exact and skillful treatment in all cases of commencing senile cataract. If we were to-day able to do less than we desired to influence the general conditions, we had some positive knowledge and ability to cope with the local conditions which attended or caused the development of cataract, and the interest of the patient demanded the application of our knowledge in every case. Nor was the consultation of the ophthalmologist justified only when a commencing cataract was feared. There was no condition leading to impairment of vision in the course of acute or chronic general disease in persons over fifty years of age that did not demand prompt and accurate diagnosis and appropriate modification of the management of the case.

In early life we did have failure of accommodation, and perhaps some other conditions leading temporarily to impaired vision during or after acute disease, which might go on to recovery without medical interference; but in persons past fifty years this did not occur; and, whether the impairment of vision had been from cataract or from some other cause, there was equal need of a full understanding of the case.

Probably the mere calling of certain forms of cataract "senile" was partly responsible for their neglect. Cataract was not due to age in the sense that arsenical poisoning is due to arsenic. It ought to be clearly understood that cataract was senile in the same sense as were fibroid kidney or arterial atheroma, and was quite as worthy of careful diagnosis and intelligent treatment. The interests of the patient demanded professional supervision; the benefit he might derive from it was as definite and unmistakable as in other diseases. And this supervision should include general as well as ocular conditions, and when it did we began to accumulate data upon which the medical treatment of cataract would be a rational procedure.

What the general conditions were that specially favored the formation of cataract, in the present condition of our ignorance, it was scarcely worth while to speculate. Perhaps the most plausible hypothesis was the one urged by the late Dr. Isaac Hays, that the lens opacity was due to a deficiency of water. This had been offered as the explanation of diabetic cataract, and that had been produced experimentally by injections of sugar and various salts beneath the skin of the lower animals. It was also favored by the evident shrinking of the lens when cataract was produced by feeding the animal with naphthalin and the subsequent clearing of such a lens when placed in water.

A hypothesis more nearly in accord with the present views of general pathology, and one probably worth bearing in mind, would be that of the formation and circulation within the body of substances which, reaching the lens by the normal course of the nutritive fluids, acted upon it unfavorably.

Briefly, the points which the author desired to emphasize by this paper were:

In general, senile change did not produce cataract, but predisposed to it.

The efficient determining causes of cataract were both ocular and general.

The general causes of cataract were not particular diseases as diseases were usually described and classified, so much as physical conditions liable to arise in the course of various diseases.

The nature, prevention, and removal of these general conditions that underlie the development of cataract offered promising fields for scientific study.

The professional supervision necessary for the making of such a study was demanded by the interests of the individual patient.

Speaking more specifically, the study of a cataract case should include the careful testing of vision at regular intervals.

The further examination of the eye to determine in how far impairment of vision was due to cataract, and in how far it was due to other causes.

The careful watching of the patient for other symptoms of impaired general health, especially for faults in the circulation, digestion, and assimilative metabolism.

Particularly at the first appearance of cataract, and at seasons of its rapid increase, would such a study of the case be of importance.

The Medical Service on Immigrant Vessels.—The American Public Health Association's committee on sanitary and

medical service on board emigrant ships presented, by the chairman, Medical Director Albert L. Gihon, of the navy, the following report at the recent annual meeting in Chicago:

Your committee beg to report the following concise statement of their views as to the organization of such a sanitary and medical service on board vessels engaged in bringing immigrant passengers to the United States as the experience and intelligence of this age make a necessity among civilized and enlightened nations. They are of opinion and advise:

First. As to the location and dimensions of the quarters for emigrant passengers, the number of berths in each, and the provisions for their ventilation and cleansing:

That the preferable location for such quarters is abaft the midship section of the vessel; that single males' quarters shall be distinct from those occupied by women and children, and that if any are forward the midship section it shall be those for single men.

That there shall never be more than two decks (properly there should be only one) occupied by emigrant passengers' berths, with sixteen feet of superficial space for each adult on the upper berth deck and twenty feet of such space on the lower berth deck, with not more than two tiers of berths on each deck, the bottom of the lower tier being not less than eighteen inches above the deck, with not less than thirty inches between the two tiers and between the upper tier and the ceiling of the compartment to allow the occupants of the berths to sit upright.

That no solid partitions or bulkheads shall be placed in any stowage compartment to obstruct light and air.

That the framework of the berths shall be of iron easily removable, that the compartment may be completely emptied and thoroughly cleaned after each passage.

That a steam ventilating apparatus by aspiration shall be introduced into all emigrant vessels; and

That all compartments occupied by passengers and crew shall be lighted by the incandescent electric light by night and day.

Second. As to the location and dimensions of hospitals on board such vessels and the number of sick-berths for which provision should be made:

That the hospitals, or "sick-bays," on board emigrant passenger vessels shall be at the extreme after part of the upper deck, thoroughly lighted and ventilated, with eighteen feet of superficial space for every fifty passengers and not less than four sick-berths or hospital cots for every hundred passengers.

Third. As to the number of medical officers proper for the maximum of emigrant passengers any vessel should be permitted to carry, being the maximum number able to be berthed with regard to health, cleanliness, and comfort:

That there should be one duly qualified medical officer for every two hundred and fifty passengers.

Fourth. As to the professional records which the senior medical officer of every such vessel should be required to keep, and his responsibility to the health authorities of the port of arrival for the truthful and professionally accurate statements of such records:

That the senior medical officer of every such vessel shall be required to keep (1) a *list of sick*, recording in a bound book, in the order of their admission, and on a single line, the name, sex, age, birthplace, date of admission to treatment, date of death or discharge from treatment, disease, and such remarks as may be necessary to enable the inspecting medical officer at the port of arrival to have a clear and complete understanding of the case, and (2) a *medical journal*, in which each medical officer, when there are more than one, shall record the medical history, including symptoms and treatment of every case, to be

approved and signed by the senior medical officer at the close of the day's record; and such list of sick and medical journal shall be submitted to the health authorities of the port of arrival, and the accuracy of the statements in such records shall be established by oath and penalties for perjury shall be provided.

Fifth. As to the location and capacity of latrines for emigrant passengers:

That the latrines—shallow troughs with a continuous flow of salt water—shall be on the upper deck under shelter with two watercloset seats for every fifty passengers, with a proportionate number for women and children, in a separate locality near their own quarters inaccessible to men.

Sixth. As to the number of attendants provided for such passengers and their duties as to policing and cleansing emigrants' quarters:

That there shall be not less than one berth-deck attendant for every fifty passengers, female attendants in the same proportion being exclusively assigned to the quarters for women and children.

That the berth decks shall be thoroughly cleansed every morning by the attendants, never wetted in rainy or damp weather, when they shall be scraped, swept, and freshly sanded, and in pleasant weather washed with hot water and quickly dried, the passengers being sent on deck during the operation.

That the berth-deck attendants shall be on duty night and day in rotation by regular sea watches, and the attendants on watch required to remove the dejecta of seasick passengers without delay; and

That benches and mess tables shall be provided and the passengers food distributed by the berth-deck attendants, who shall take away all unused food and carry the dishes to the pantry.

Seventh. As to additional provisions for the personal health, cleanliness, and comfort of emigrant passengers:

That wash rooms under cover with basins supplied with running water shall be provided on the upper deck, those for men to be separate from those intended for women and children.

That fresh water for drinking purposes shall be provided in each compartment; and

That inexpensive mattresses, pillows—these to be serviceable as life preservers—and blankets shall be provided for emigrant passengers, the mattresses to be destroyed after each passage, and the pillows and blankets to be steamed and washed before being again used.

While other suggestions as to sanitary provisions might appropriately be made, your committee feel that those indicated are of such urgent necessity that they should be insisted upon and put into effect without delay.

All of which is respectfully submitted:

ALBERT L. GIHON,

Medical Director, U. S. Navy, Chairman.

FREDERICK MONTIZAMBERT, M.D., F.R.C.S., D.C.L.,
Supt. Quarantine Station, Grosse Ile, Quebec.

WALTER WYMAN,

[Signed.] *Supervising Surgeon General, U. S. M.-H. S.*

S. R. OLLIPHANT, M. D.,

President of the State Board of Health of Louisiana.

WILLIAM T. JENKINS, M. D.,

Health Officer of the Port of New York.

The Effects of Tight Lacing.—The *American Woman's Illustrated World*, says the *Sun*, prints the result of an interesting experiment made by a dozen young women under the

direction of Dr. Sargent to determine the influence of tight clothing upon the action of the heart. The test was the running of four hundred and forty yards in loose gymnasium garments, and covering the same distance with the corsets on. The running time was two minutes thirty seconds for each trial, and in order that there should be no cardiac excitement or depression following the test, the second trial was made the next day. Before beginning the running the average heart impulse was eighty-four beats to the minute. After running the above-named distance the heart impulse was one hundred and fifty-two beats to the minute, the average natural waist girth being twenty-five inches. The next day corsets were worn during the exercise, and the average girth of waist was reduced to twenty-four inches. The same distance was run in the same time by all, and immediately afterward the average heart impulse was found to be one hundred and sixty-eight beats per minute. Dr. Sargent says that he never feels justified in advising an athlete whose heart impulse is one hundred and sixty beats per minute after a little exercise to enter a running or rowing race, and from this may be inferred the physiological loss entailed upon the system in women who force this important organ to labor under the disadvantage of a tight corset.

The late Dr. D. J. Macgowan, of China.—The *China Medical Missionary Journal* for September contains the following memorial article, written by Dr. William Muirhead:

We are called to record the demise of our venerable friend Dr. Macgowan. It took place on the 20th of July after a few days' illness, and in the seventy-ninth year of his age. He was long and well known in China, and highly esteemed by a large circle of friends. His death, so sudden and unexpected, in the very midst of his usually active life, and in the prospect of still further useful service, has left a wide gap, which it is painful on the part of many to realize. However, he had arrived at a good old age, and we can only take a cursory view of the man, his manner of life, his Christian character, and the work he has done in his day and generation.

Necessarily the details to hand are few, and we know no one who could furnish particulars of many things in the past history of our friend, yet these may not be required to supply the general outline we contemplate, or add to the high estimate we have formed of the subject of our sketch.

Dr. Macgowan was born in Fall River, Mass., and came to Ningpo as a medical missionary in connection with the Baptist Missionary Union in the year 1843. This was at the first opening of the country, and though we have no account before us of his services in these early days, we may be assured he was eminently useful, like others in the same capacity, ministering to the wants of the sick and diseased in the neighborhood. The valuable *Chinese Repository* doubtless contains particulars of his work, and information of various kinds from his pen, which he was always so ready to furnish, but we need not refer to this at present.

On his return to the United States, in the time of the civil war, he served as a surgeon in the Northern armies, and made himself much respected in Washington. He came back to China in 1865 and took up his quarters in Shanghai. He began medical practice among the shipping, which was found to be a difficult and precarious thing for a man of his age, but he persevered in it as long as he possibly could. He had married a most excellent and accomplished lady, who was an English governess in Calcutta, and was a great comfort and help to him in his missionary life and subsequently. They had two children, but one died very young, while the other is the wife of Sir Chaloner Alabaster, now in England. About the year 1878 Mrs. Macgowan died in Shanghai, which was a lifelong sorrow

to our departed friend. It rendered him all the more unfit to carry on his work here single-handed and alone. Happily, Sir Robert Hart provided a situation for him in the customs service at Wenchow, which was a benefaction of very great value for a number of years.

While our friend was thus engaged he had leisure, as he had talent, disposition, and learning, to prosecute a variety of studies, both in Chinese and English. He was exceedingly given to this kind of thing, ever inquiring into folklore and scientific themes, familiar and out of the way, and never failing to communicate the result of his researches to public papers at home and abroad. The records of different societies, especially the Royal Asiatic Society of this place, abound with articles of his contribution, and the *North China Daily News* and the *Shanghai Mercury** were favored in no small respect in this way.

During the last year, when freed from his official-work, he undertook a journey to Japan and the Loo-choo Islands. There he came in contact with the high authorities, and while adding to his information on various subjects he had the opportunity of giving them important advice on education and civil government. On returning to Shanghai, he prepared at once to go North, as he had done previously to Manchuria and Siberia, where he was engaged on some interesting investigations. On his last journey he regaled his friends of the Oriental Society of Peking with the result of his inquiries in Japan on several points of ancient history between the two countries.

On the 15th of July he came back to Shanghai, and called the same afternoon on the writer with a long paper he had composed on the Geary Exclusion Act. He was deeply concerned about this matter, and his object was to get his paper translated into Chinese, for publication in the native newspapers here in the first place, after which he intended to proceed to Washington to present it to the President of the United States. He was promised letters by Li Hung-chang to the Chinese Minister in the States, with whom he could negotiate the subject. When he had carried this matter through, his purpose was to proceed to England and spend the remainder of his days in the family of his beloved daughter. The hand of Divine Providence, however, was upon him, and after a few days' illness he died, it appears, from sheer exhaustion, and was buried in the beautiful cemetery of our foreign settlement, in the presence of a large number of friends and acquaintances.

A word or two in regard to the Christian life and character of the deceased. Though long separated from missionary work, in so far as actual engagement in it was concerned, there was no cessation of his interest in it, or in the maintenance of his religious profession. He was in this respect faithful to the end, and it was pleasant to observe this at his advanced period of life, and in the midst of other things that he was following out. The writer can testify to incidents of this kind that are gratifying to think of, and which led him and others all the more to esteem and respect him. As to his general manner and appearance, he was rather small in stature, and his long white beard made him look most venerable, while at the same time he was most genial and youthful in his intercourse with friends, his remarks often sparkling with witticisms of an amusing and interesting kind. He was well informed in current events and discoveries, and ever ready for conversation about them, yet underlying the whole there was a supreme interest on his part in the power and progress of Christian truth. Attached to his own line of things as a Baptist, there was no narrowness of mind in relation to other views and parties, and

* Dr. Macgowan was an occasional writer for our *Journal* and but shortly before his death promised us a series of articles for it.—Ed. CHINA MED. MIS. JOUR.

withal we cherish his memory and lament his loss, while the blessed hope remains that all is well, and having served the Master in his life on earth, he has entered on a gracious reward above.

Einhorn's Gastrodiaphane.—At a recent meeting of the College of Physicians of Philadelphia Dr. S. Solis-Cohen said:

I wish to call the attention of the fellows of the college to the gastrodiaphane devised by Dr. Max Einhorn, of New York, which consists of a small electric lamp fastened to a flexible stomach tube with cords connecting it with a source of electric power and with a handle to make and break the current. Four storage cells having an electromotive force of eight volts, or an equivalent number (six) of freshly charged bichromate primary cells, will operate it. The patient having swallowed two glasses (one pint) of cold water, the end of the tube is lubricated with glycerin, and the instrument is then readily swallowed by a person accustomed to swallow the stomach tube and sometimes by those not accustomed to its use. The examination being made in a dark room, when the current is turned on, the contour and area of the stomach appear very plainly as a luminous red zone on the abdominal wall. The advantage of this method is in determining the presence or absence of thickening in the anterior wall of the stomach, and in determining the exact position of the stomach and the outline of the lesser curvature. It is exceedingly useful in diagnosing between dilatation of the stomach and the condition termed gastroptosis or sinking of the stomach. I have used the instrument in many normal-sized stomachs and in half a dozen cases in which diagnosis was in doubt. In one case it confirmed the diagnosis of dilatation where the ordinary methods of percussion were unsatisfactory, thus proving the presence of pyloric obstruction, although the cause of the obstruction was so situated as not to be manifest. In another case, with symptoms of carcinoma and absence of free HCl, but in which a tumor could not be felt, the thickening of the anterior wall appeared very clearly on the abdomen as a dark patch in the midst of the zone of transillumination. In another case in which there was a question whether or not a tumor of the abdominal wall communicated with or was attached to the stomach we were able to demonstrate that there was no direct connection.

The method has a limited usefulness in diagnosis, its advantage being that it is readily applied and that within its limitations the information it gives is easily interpreted.

Dr. D. D. Stewart said: I have used gastrodiaphany for about a year in quite a large number of cases. I have found that the introduction of but one or two glasses of water is not sufficient to render the whole stomach translucent. It permits only the lower part of the stomach—that of the greater curvature—to be seen. Heryng and Reichmann advise the introduction of 1,000 to 2,000 c. c. of water. In this way the lesser curvature is also outlined. At times you can see a portion of the colon illuminated, the recti muscles, the hypogastric veins, and also the edge of the liver and a portion of the spleen. The great objection is the difficulty of getting the patient to swallow the diaphane. One has first to become used to the tube. For gastrodiaphany to be of any diagnostic use it is necessary to introduce so much water that it causes great discomfort to the patient, and often vomiting, necessitating prompt withdrawal of the instrument.

Dr. Frank Woodbury said: This instrument was first presented to the German Practitioners' Society of New York five or six years ago and its use demonstrated. It has not made very great progress since then. If we have to administer a couple of quarts of water before making the examination the diagnosis of

dilatation is already made. Where we suspect a growth on the anterior wall of the stomach it might be advantageous to use this instrument. I would suggest instead of glycerin as a lubricant the use of cacao butter, which is a bland and entirely unobjectionable material.

Dr. Stewart said: With reference to lubricants for stomach tubes I would say that I use nothing save water. Glycerin is unnecessary and cacao butter is not to be thought of.

Dr. Solis-Cohen said: Einhorn maintains, and I agree, that one advantage of his instrument and method over Heryng and Reichmann's lies in the small quantity of water necessary. Einhorn has also the priority in the matter, if that is of any consequence. Glycerin is used to lubricate the glass only, and I find it useful and without drawback of any kind.

Cleft Palate in Lions born in Captivity.—In a paper on Cleft of the Hard and Soft Palates, read at a recent meeting of the Philadelphia Academy of Surgery, Dr. J. Ewing Mears stated that observations made in the Dublin Zoological Gardens some years since had quite positively determined that the condition might be due to a want of proper nutrition in the mother during the period of gestation. Up to the time referred to it had been impossible for the authorities in charge of the garden to rear the young of the lion, on account of the invariable occurrence of cleft of the palate, which prevented the taking of nourishment to maintain life. The plan of giving to the mother during pregnancy ground bone and food containing the inorganic elements of bone had been crowned with success, and within recent years a large revenue had been derived from the sale, to all parts of the world, of lions raised in this garden. The lion whelps in the Zoological Gardens of Philadelphia had suffered in the same manner, and he had suggested to the superintendent to adopt the plan practiced in the Dublin garden. During the conversation the superintendent had stated an interesting fact: that the whelps of lions in traveling menageries did not suffer like those born of mothers confined in gardens, and he was disposed to account for the fact by the rough life led by them, as well as by the variety in the food, consisting of bones as well as of meat—sometimes more of the former than of the latter.

Salipyrine in the Treatment of Uterine Hæmorrhage.—The *Revue générale de médecine, de chirurgie et d'obstétrique* for November 15th gives a summary of an article by Dr. Kayser, published in the *Deutsche medicinische Wochenschrift*, who gives his experience in the treatment of a number of cases of uterine hæmorrhage with salipyrine. He has employed the drug in sixteen cases, but in three of them the hæmorrhage was too severe to allow of a sufficiently prolonged trial of it. In all but one of the thirteen other cases the use of salipyrine reduced the hæmorrhage, no matter what its cause was, excluding cancer and abortion. In some of the patients the hæmostatic effect lasted for several days after the use of the medicine had been suspended. It had no effect on pain. It was especially efficacious in cases of menorrhagia coming on at the time of the menopause. It was well borne in every case, but with two or three of the patients it caused a little ringing in the ears. It was given in powder or in the form of compressed tablets, in doses of fifteen grains three times a day. As nearly as possible its administration should be begun on the day before a menstrual period is expected.

The Pious Apothecaries of Antwerp.—The *Deutsche medizinische Zeitung* condenses from a Scandinavian medical journal the statement that three out of the four apothecaries of Antwerp have recently resolved to close their shops at two o'clock in the afternoon on Sunday.

Original Communications.

THE DIAZO REACTION OF EHRlich.*

By JULIUS FRIEDENWALD, A. B., M. D.,

DEMONSTRATOR OF PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS,
BALTIMORE; VISITING PHYSICIAN TO BAY VIEW HOSPITAL;
ATTENDING PHYSICIAN TO THE MEDICAL DEPARTMENT,
CITY HOSPITAL DISPENSARY.

SINCE Ehrlich† first introduced his "new urinary test," the diazo reaction, into clinical medicine it has been the object of much interest, for it is simple and easily carried out and of great diagnostic value. Many objections were at first offered, but these were soon proved to depend upon errors in the performance of the test.

Year by year the reaction has gained new adherents, so that it is now considered a very efficient diagnostic measure in most of the clinics of Germany and of many other countries.

In recent years new objections have been raised, and it is the main object of this paper to show that these are unwarranted.

The diazo reaction depends upon the principle that if sulphanilic acid (amidosulphobenzol) is acted on by HNO_2 , diazosulphobenzol is formed, which unites with certain aromatic substances (of the urine) to form aniline colors.

To obtain diazosulphobenzol in a fresh condition, sulphanilic acid is kept in solution with hydrochloric acid; to this sodium nitrite is added, whereupon HNO_2 is liberated and diazosulphobenzol is formed.

The reaction is carried out in the following manner:

Two solutions are prepared:

(a) Two grammes of sulphanilic acid; fifty cubic centimetres of hydrochloric acid; one thousand cubic centimetres of distilled water.

(b) Five-tenth-per-cent. solution of nitrite of sodium.

In order to perform the reaction, fifty parts of a and one part of b are mixed, and equal parts of this reagent and of urine placed in a test tube and saturated with ammonia. In those cases in which the reaction is positive the solution assumes a carmine-red color, which, on shaking, must also be visible in the foam. If the test tube is allowed to stand twenty-four hours, a greenish precipitate is found.

Ehrlich‡ arrived at the following conclusions:

1. The reaction is most commonly found in typhoid fever from the middle of the first week; and that whenever the reaction is missing the diagnosis appears doubtful.

2. Cases of typhoid fever in which the reaction is slight and only found for a short time are usually very mild.

3. In phthisis pulmonalis the reaction is a grave prognostic sign. The reaction is sometimes, but rarely, found in measles, miliary tuberculosis, pyæmia, scarlet fever, and erysipelas.

4. In all diseases unaccompanied by fever—such as

chlorosis, hydræmia, diabetes, brain, spinal, liver, and kidney diseases—the reaction is never obtained.

These postulates of Ehrlich's were verified by his pupils and others.

Fisher* obtained the reaction constantly in measles and very frequently in typhus fever. This proves that the substance causing the reaction can not bear any relation to the chemical changes going on in the typhoid intestine, as such are entirely absent in these diseases.

Brecht† corroborated the statements of Ehrlich. He found the reaction in seventeen cases of typhoid fever, two cases of measles, and rarely in pneumonia. The appearance of the reaction in pneumonia is to be regarded as of grave significance.

In other non-febrile diseases the reaction could not be obtained.

Löwinson,‡ after making numerous investigations, especially in pulmonary tuberculosis, came to the following conclusions, which entirely accord with those of Ehrlich—namely:

The appearance of the reaction in tuberculosis is a *signum mali ominis*. It is not dependent upon the fever. Marked reactions lasting for a long time (one to two months) are only found in tuberculosis, and especially in the most rapid forms.

Cnopf§ and Grundies|| arrived at the same general conclusions concerning tuberculosis.

Escherich,^ See, & Dorendorff‡ also corroborated Ehrlich's investigations.

Goldschmidt‡ found the reaction constantly in miliary tuberculosis and typhoid fever, and remarks that the reaction is of great value in the diagnosis between typhoid fever and gastro-intestinal catarrhs running their course with fever. He did not find the reaction in influenza.

Spiedhoff‡ made experiments to discover the cause of the red diazo reaction, and found that neither diacetic acid nor æthyldiaceticæther give the true reaction. In order to obtain a reaction with these substances, stronger solutions (NaNO_2) are required. He therefore warns against the use of too strong reagents in performing the ordinary diazo reaction. He considers the reaction of great prognostic and diagnostic importance in tuberculosis and typhoid

fever. He states that true reactions show the green precipitate.

Loewe* finds the reaction to be one of the most constant of the signs of typhoid fever, and absence of the reaction he believes is sufficient to make the diagnosis doubtful. Of thirty-one cases of typhoid fever, he missed the reaction only in four.

Georgiewsky† admits the high prognostic value of the reaction.

Brewing,‡ who made twenty-five hundred examinations, finds the reaction of great diagnostic and prognostic value in typhoid fever, phthisis, puerperal affections, and concealed septic processes.

Roessingh* and Piering|| likewise confirmed Ehrlich's statements.

Rüttemeyer,^ after a series of exact experiments, came to the following conclusions:

1. The diazo reaction is of great diagnostic value in typhoid fever; next to the enlargement of the spleen and roseola, it is one of the most constant and earliest signs.

2. The diagnosis of typhoid fever gains much certainty if the diazo reaction be present; if, on the contrary, the reaction is absent during the first and second weeks of the illness, the disease is not typhoid, or only a very light form.

3. Gastro-intestinal catarrhs accompanied by fever never give the reaction.

4. The reaction bears no relation whatever to the height of the fever and is not influenced by various medicinal or therapeutic measures (baths, etc.). Morning urine and evening urine give reactions of equal intensity.

5. If the reaction terminates in the second or third weeks of the disease an early fall of the fever and a mild course of the disease may be expected, but long continuance of the reaction indicates a severe and lengthy course of the disease.

6. Marked and continuous reactions do not, however, in any way indicate whether the disease will terminate fatally or favorably.

7. In relapses we almost always get a renewed reaction if the reaction has disappeared before the relapse occurs.

Simon◇ considers the appearance of the foam as characteristic of the reaction and finds the reaction only in typhoid fever and tuberculosis. Of thirty cases of typhoid fever, the reaction was present in twenty-six.

C. Gerhardt‡ states that in his clinic during five years the reaction was absent in but one certain case of typhoid

fever; on the other hand, he has found the reaction present in non-febrile cases of typhoid fever, numerous cases of which were at the Charité in the spring of 1891.

Von Norden's* experience at Gerhardt's clinic coincides with the statements of Ehrlich. The rise of temperature as such has no marked influence on the appearance of the reaction, for even severe cases of phthisis, running their course without fever, show marked reactions for weeks. In phthisis a continuous reaction denotes special severity of the case and makes the prognosis unfavorable. In typhoid fever the reaction is so constantly present at the beginning and during the course of the disease that we must be doubtful of our diagnosis of typhoid when the reaction is absent.

It is not unlikely that in those rare cases of gastro-intestinal catarrh in which certain authors detected the reaction the disease was really non-febrile typhoid fever.

Pape† made observations regarding the diagnostic value of the diazo reaction in surgical tuberculous affections, and found that after every operation the reaction which had previously been present disappeared—in some immediately after the operation, usually within three to five days.

Worthing‡ found the reaction in only a few diseases and arrives at conclusions fully in accord with those of Ehrlich. He points to the importance of relying only on the red color in the foam.

Notwithstanding the many observations showing the diagnostic and prognostic value of the diazo reaction, certain writers make statements quite contrary to those of Ehrlich.

Penzoldt* and Petri|| were the first to attack Ehrlich's conclusions. They deny that any marked difference existed in regard to the reaction between healthy persons and patients, even those having fever. It is not necessary to prove here the error into which these writers had fallen.

Ehrlich himself showed that these authors used solutions of sodium nitrite much too concentrated. Concentrated solutions produce a pseudo-reaction, which may even be so marked as to cover a true reaction. The reaction should always be made with weak solutions of sodium nitrite (one half per cent.).

It is remarkable, however, that, though these objections have been so thoroughly answered by Ehrlich and the reaction has been proved to be of great value, von Jaksch,^ in the new edition of his *Clinical Diagnosis*, "disclaims for the test any clinical importance whatever, and especially enjoins the necessity of avoiding inferences based upon the appearance of the reaction."

He believes that the color when obtained is always due to the presence of acetone. He bases his conclusions on

the old Penzoldt and Petri statements and on a discussion before a medical society* without bringing forward any personal investigations on this subject. His conclusions can not be accepted, for—

1. Von Jaksch does not perform the reaction correctly. After adding sulphuric acid and sodium nitrite to the urine, he does not saturate with ammonia.

2. Because he states that Ehrlich recommends the addition of five to six volumes of absolute alcohol to the fluid to be tested, and then drop by drop the reagent. Ehrlich recommends this procedure only for his bile test, not for this urinary test.

3. It is impossible to demonstrate the presence of acetone by means of this reaction, performed according to the method of Ehrlich, as I have already shown in the first part of this paper. I have frequently convinced myself of this fact.

Of still less value is the article of Monson and Oertel,† who endeavor to identify the substance producing the reaction as diacetic acid and to show that the reaction is the same as that obtained by means of Gerhardt's iron test. If Monson and Oertel had read the experiments of Spiedhoff,‡ which were made under Ehrlich's direction, they would have learned that Ehrlich long ago pointed to the fact that diacetic acid and ethyl diacetate gave a reaction with the diazo reagent; that, however, a stronger solution of the reagent was needed (NaNO_2), and that the red color was heightened with ammonia or even caustic potash. More characteristic, however, is its relation to mineral acids, for, while small quantities turn the red color into yellow, large quantities change the yellow into a violet.

Warthin* has also proved that the substance occasioning the reaction must be quite different from diacetic acid.

In answer to the statements of authors, such as Edwards,|| who find the reaction accompanying all forms of diseases with or without fever, we assert that the reaction has been wrongly performed by these writers.

1. Very weak reagents (one half per cent. NaNO_2) must be used.

2. The alcohol test is not to be employed.

3. A positive reaction is only one in which the red reaction is present in the foam.

My own observations with the diazo reagent includes over three thousand reactions.

Twenty-one cases of typhoid fever were examined; the reaction was absent in but one case. I subjoin a synopsis of the typhoid-fever cases in which the reaction was used:

CASE I.—First examination was made on the fifth day of the disease: reaction was present daily until the twenty-second day. The case ended in recovery.

CASE II.—First examination on the fourth day: reaction present on the fifth day and continued until the twenty-sixth day.

CASE III.—First examination on the fifth day: reaction present and continued until the twentieth day.

CASE IV.—First examination on the eighth day: reaction present until the nineteenth day.

CASE V.—Only two examinations were made: reaction present on the tenth and twelfth days.

CASE VI.—First examination on the sixth day: although daily examinations were made, the reaction was not present until the eleventh day; it continued from then on until the fifteenth day. This was an extremely mild case.

CASE VII.—Only one examination made: reaction present on the eleventh day of the disease.

CASE VIII.—First examination on the fifth day: reaction present until the eighteenth day.

CASE IX.—First examination on the third day: reaction first present on the fifth day and continued until the fifteenth day.

CASE X.—First examination on the sixth day: reaction present from then on daily until the nineteenth day.

CASE XI.—First examination fifth day: reaction present and continued till the twelfth day, on which the patient died.

CASE XII.—First examination second day: the reaction was found on the fourth day and continued until the nineteenth.

CASE XIII.—First examination on the eighth day: the reaction was present, and continued until the fourteenth day.

CASE XIV.—First examination third day of the disease: reaction found on the fourth day and continued until the twenty-fourth day.

CASE XV.—First examination on the fifth day: reaction then present and continued until the twentieth day.

CASE XVI.—First examination fifth day of the disease: reaction present on the seventh day and continued until the twelfth day.

CASE XVII.—Only one examination made: reaction present on the seventh day of the disease.

CASE XVIII.—First examination eighth day of the disease: reaction not present; repeated examinations were made daily for ten days. The case was exceedingly mild, with a temperature never above 102.5°F .

CASE XIX.—First examination fifth day of the disease: reaction first present on the seventh day and continued daily until the twenty-second day.

Case.	Day of first examination.	Day of first appearance of reaction.	Day of last appearance of reaction.	Remarks.
1	5th day of disease.	5th	22d	Twelve days also reaction; only two examinations made.

|| Edwards. *Medical News*, April 2, 1892.

CASE XX.—First examination on the fourth day of the disease: reaction present and continued until the fourteenth day.

CASE XXI.—First examination on the fourth day of the disease: reaction first observed on the fifth day and continued until the twentieth day.

From these observations in typhoid fever it may be concluded (1) that the reaction is very constant in this disease; (2) that it makes its appearance usually within the first week; and (3) that the reaction gradually disappears between the end of the second and third weeks.

Examinations were made in forty-three cases of pulmonary tuberculosis. Of these, twenty-nine were severe cases, with almost constant reaction; fourteen were light forms which did not show the reaction. Of the twenty-nine severe cases, twelve died while still under observation; eight are still under observation in an unimproved condition.

The presence of the reaction in this disease, extending over long periods of time, may therefore be regarded as a grave sign.

The reaction was also found to be present in three cases of erysipelas (for several days), in one case of bone abscess (tuberculous) in one case of liver abscess, in one case of suppurative glandular disease of the neck, in one case of tubercular hip-joint disease, in one case of tubercular spinal disease, in one case of pneumonia (very grave case—died), in one case of carcinoma ventriculi, and in one case of septicæmia.

The reaction was never obtained in healthy individuals; it was not found in four cases of cerebral disease, eight cases of spinal-cord disease, five cases of lung disorder excluding tuberculosis (six cases of pneumonia), four cases of heart disease, two cases of abscess of the liver, ten cases of cirrhosis of the liver, nine cases of gastric disorder (seven cases of cancer of the stomach), twelve cases of gastro-intestinal catarrh with fever, thirty-four cases of gastro-intestinal catarrh without fever, seven cases of dysentery, nine cases of nephritis, eight cases of bladder disorders, sixteen cases of other genito-urinary disorders, ten cases of rheumatism, eleven cases of diabetes (four of which gave Gerhardt's diacetic-acid reaction), five cases of abscess, five cases of hysteria, two cases of epilepsy, two cases of neuritis, eight cases of syphilitic disorders, three cases of skin disease (one case of lupus), two cases of diphtheria, two cases of erysipelas, twenty-one cases of malaria, three cases of sarcoma, five cases of carcinoma, and nineteen cases of injuries of various kinds.

My own observations, therefore, entirely confirm those of Ehrlich. In conclusion, I shall again emphasize Ehrlich's statements:

1. The diazo reaction is of great diagnostic value in typhoid fever.

2. If the case shows a slight or no reaction between the fifth and eighth days, other appearances pointing to typhoid fever, it can be looked upon at once as an exceedingly light form and the prognosis made accordingly.

3. Gastro-intestinal catarrhs accompanied by fever always run their course without a reaction.

4. Very marked and constant reactions may accompany mild forms of typhoid fever and do not justify a bad prognosis.

5. Reactions appearing continuously for a long time in phthisis pulmonalis (two months) always indicate a grave prognosis.

RECENT STUDIES

IN NAUPATHIA, OR SEASICKNESS.

SYMPTOMATOLOGY, DIAGNOSIS, PATHOGENESIS, AND TREATMENT BY A NEW AND EFFICACIOUS METHOD.

By WINSLOW WARNER SKINNER, M. D. (PAR.),
FORMERLY SHIP'S SURGEON ON SEVERAL TRANSATLANTIC LINES, ETC.

(Continued from page 723.)

V. We come now to the most practical chapter of this work—that which concerns the therapeutics of seasickness.

A. *Prophylaxis*.—In regard to the prophylaxis of naupathia, we know of no precautions or remedies for its prevention that are always efficacious, but there is much that one can do to avoid this affection with more or less success.

In the first place, the mental state of the voyager is of great importance. The firm will, the determination not to be sick, is useful up to a certain point. Again, as has been already remarked, the lively interest in the voyage itself, the keen enjoyment of this mode of travel, have often prevented a person from feeling sick while the novelty of the situation lasted.

Various kinds of apparatus have been tried to annul the movements that the body undergoes when aboard a ship during the rolling and pitching. Thus M. Neveu-Derotrie invented an easy chair, made to hold a person always in an upright position. But it failed to obviate all the trouble. M. A. Déchambre has very justly observed that this chair can not avoid following the rise and fall of the ship, which are the most disagreeable movements of all. We would add that the lateral movements of the ship also can not be avoided by using this apparatus.

According to a principle similar to the one embodied in the easy chair, suspended saloons have been constructed upon certain ships. Messrs. Bessemer & Reed constructed in this way a boat called the Bessemer. Movements due to rolling may, according to the theory, be thus avoided, but not movements due to pitching (or those taking place in a vertical plane), which are the terrible ones. At all events, the trials of this steamer were not successful. Attempts of this kind have doubtless been abandoned.

Another effort to annul the effect of the waves was made when the steamer Calais-Dover was built. It consisted of two hulls fastened together—a sort of nautical Siamese twins. It was hoped that rolling and pitching would be checked by this combination before they caused much discomfort, but this experiment also proved a failure. The double boat is being used at present as a marine hospital in the Thames, near London.

Large ships are naturally less tossed about than small ones are; therefore it is advisable for one susceptible to seasickness to select a large ship for his voyage. But more important still is the situation occupied by the passenger.

Thus the middle of the ship is the most favorable for the avoidance or the cure of naupathia, since the motion is here the least. For this reason, as is well known, a berth amidships is the most desirable for a person likely to be sick. A stateroom as near as possible to the ship's center of gravity is the best.

A person standing or sitting is more exposed to seasickness than a person lying down. Hence the recumbent position should be assumed by all who wish to recover from an attack, or, being in danger of it, wish to escape it. This fact is in direct accordance with our theory of the cause of seasickness, and brings a strong confirmation of it.

Many authors (Jobard, Fischer, Kéraudren, Fonssagrives) recommend binding the abdomen by means of a broad bandage. Our own personal experience with it convinces us of its usefulness. It certainly gives great relief, and affords a needed support to the abdomen when exhausted by incessant retching and vomiting. One of our lady patients testified to its utility by saying she could not live without it. The bandage employed may be only a towel or napkin, carefully pinned or sewed around the body so that it will fit the abdomen. It should be wide enough to compress the abdomen from the xiphoid appendix to the pubis without being so tightly drawn as to notably impede respiration. If the abdomen should become so hollow as to render it impossible to accurately fit a bandage around it, the hollowness may be filled up by a soft blanket folded smoothly and fitted into the depression which is most considerable in the lower portion of the region—*i. e.*, between the ossa ilia.

So much for the mechanical means of prophylaxis. They obviate to some extent the sufferings of seasickness. Let us turn now to the pharmaceutical means about which the same remark applies.

Alcohol in various forms has often been tried by voyagers on embarking who fear the sea. The effect of this agent is uncertain. Some are doubtless helped by it. The same is true of ethylic ether. Certain aromatics have a short favorable effect on a few individuals. The most used are peppermint and cloves. Smelling-salts sometimes ward off the first feeling of nausea, the forerunner of naupathia.

Other substances have rendered real and undoubted service in prophylaxis. They are chloral hydrate, the bromides, morphine, antipyrine, quinine, and, according to some writers, cerium oxalate. Dr. Pritchard (*Lancet*, 1871) has, for one, tried the first-named agent with great success during the short crossing from Dover to Calais. He took enough, however, to put him to sleep.

The sodium and potassium bromides, taken during the three or four days immediately preceding embarkation, have occasionally proved effectual. A drachm (four grammes) per day should be taken in divided doses. Morphine has been recommended, but we have had no personal experience with it as a prophylactic.

Sulphate of quinine in the dose of one gramme (fifteen grains), taken four hours before embarking, has recently been praised by Dr. Ch. Richet, of Paris.

All of the above substances operate by diminishing the reflex activity of the nervous centers, which we have seen

to be one of the chief factors in the causation of seasickness. They also (excepting, perhaps, quinine) produce sleep if pushed far enough, and thus they suspend all consciousness of suffering. Pushed to that extent, however, they deprive one of the pleasures of the voyage, as well as save one from discomfort.

There is an entire class of substances which, according to theoretical views, ought to produce a favorable prophylactic result, and these are the so-called *neuromuscular* agents or drugs, some of which have actually been proved useful. All of these substances, nevertheless, are not equally effective. The following alkaloids, which until recently have been classed among the moderators of nutrition, possess properties that justify their admission into the neuromuscular group. These are cocaine, caffeine, theine, and perhaps also theobromine, guaranine, and kolaine. Taken in suitable quantities, these substances increase the activity of the nerve cell and of the unstriated muscular fiber, as well as that of the striated. Thereupon result several effects, of which the principal one which interests us is the *elevation of the arterial blood pressure*. A great number of experimenters have verified this fact, and we have also repeated these experiments with a similar result.*

Cocaine has often been efficacious as a preventive of seasickness. It acts by producing sometimes sleep, sometimes mental stimulation, sometimes, it is believed, augmentation of the blood pressure, as experimenters have shown many a time. Its action, though, is not uniform, and we have seen this alkaloid produce very alarming accidents in seasick women. Several times after it had been taken the number and violence of the vomitings increased. Once a woman having received a hypodermic injection of 0.05 gramme (five centigrammes) of cocaine chlorhydrate presented dangerous symptoms half an hour afterward. The heart beat 180 times per minute; the eyes were red, injected, and tearful; the pupils were ecstatic. She had paroxysms of alternate nervous laughing and crying, and did not seem to understand questions addressed to her. Her replies were vague and incoherent, or else she did not reply at all. This state lasted twenty minutes, after which the pulse fell to 134 and its tension increased, and her replies became clear. Since then we have not injected cocaine in naupathia. Administered *per orem*, however, cocaine has a good effect.

Caffeine and coffee are excellent remedies in this affection. More will be said of them and of cocaine under the rubric of curative treatment. We can strongly recommend voyagers subject to seasickness to take a cup of a good infusion of pure coffee, pretty strong, at the moment of feeling the *first indications* of the approach of the trouble—*i. e.*, at the first suspicion of nausea, vertigo, prostration, headache, or even of greater paleness of the face than usual. If one waits too long, the stomach will no longer be in a state to absorb anything, for as the sickness increases the stomach is going to secrete a lot of watery mucus which will be ejected by emesis and the coffee with it.

* W. Skinner. Les effets pharmacodynamiques de certains alcaloïdes, etc. *Bull. gén. de thérapeutique*, July 15, 1886, p. 29.

The coffee beans for this infusion should be quite ripe so that they shall contain the maximum of caffeine, and should be moderately torrefied in hot air to favor the formation of a certain quantity of caffeine. The infusion should be taken hot and but slightly sugared, if at all, but the dose should not be repeated too often, for it has been noted that a secondary lowering of the blood pressure has occurred upon the ingestion of too much caffeine. In any case, after the lapse of one or two hours, if the need of a new dose makes itself felt, one might take a strong infusion of black tea (pekao tea if obtainable) in the proportion of three grammes (forty-five grains) of tea to a hundred grammes of water, for, in spite of the identity of theine and caffeine as to their chemical formula, tea does not produce quite the same effect as coffee.

B. Curative Treatment.—The curative treatment of naupathia has up to the present time been much neglected, and when means have been employed they have been of great diversity, and usually inefficacious. So true is the last statement that nearly all ship physicians wholly renounce all attempts to cure the affection and content themselves by merely offering a few suggestions toward palliation, and the patients themselves are generally resigned to await the spontaneous termination of their woes without disturbing the doctor. We see no reason why this state of helplessness should last any longer, for our endeavors to find a remedy have resulted in the employment of a therapeutic method quite simple in itself yet followed by almost constantly favorable effects.

Before entering into the details of our new method, a word may be said of the few other methods of treatment which have also been suggested by purely theoretical views of the nature and cause of seasickness. Thus Sémanas prescribed quinine sulphate for his imaginary marine miasm. Chapman advised the application of ice along the vertebral columns by means of his special apparatus or spinal ice bag in order to combat the supposed abnormal afflux of blood in certain parts of the spinal cord. We have never known a case in which it was tried, and its application would seem *a priori* inconvenient and disagreeable. Le Coniat practiced with more or less success the faradization of the epigastrium and the hypochondriac regions, employing conjointly with this the painting of a solution of atropine (0.02 to 0.05 gramme in thirty grammes of water) over the region of the stomach. He claims to have obtained really good results, but he did not begin his treatment during the first day of the sickness. This delay permitted the patient to get well, or nearly well, spontaneously, so that one can not tell how much of the cure was due to treatment. Then again the absorption of a certain quantity of atropine would alone cure a mild case.

Antipyrine as a curative agent has been loudly vaunted by some ever since the communication of Dr. Ossian-Bonnet to the Academy of Medicine of Paris in 1887. This author advises antipyrine to be given in the dose of one gramme (gr. xv), repeated if necessary until the patient is better. He gives it also subcutaneously if vomiting is severe. Our own limited experience with this drug was unsatisfactory.

Cocaine has cured some cases, and a former colleague of the author's, Régnault, of Paris, has published results of this treatment (*Progrès méd.*, 1887). The doses of this powerful drug that he gives, however, are, in our opinion, eminently dangerous. But we have said in another place that cocaine given in small doses by the mouth is an excellent remedy.

There is an unusually effective and agreeable combination of medicines put up in liquid form and known as naupathic elixir, which has shown itself to be very useful in preventing and curing seasickness. It is said to contain seven different ingredients, each of which has been found helpful in this affection, and two of these are known to be caffeine and cocaine. It is sold by Hazard, Hazard, & Co., of New York. We have personally tried this elixir on several of our voyages as ship's surgeon, and have found it to be very grateful to our patients.

The treatment upon which we rely with the greatest confidence, however, is that about to be described. We were led to choose the two substances which form the base of the medication in the following manner: After having studied the symptoms of naupathia in their completeness, as if no physician had ever seen or written about them before, we were convinced that they were due, above all, to the lowering of the blood pressure, as has been already said, and that this lowering depended upon a paresis of the centers of innervation of the heart and of the arteries, as was above explained. There only remained, then, to choose from the *materia medica* the suitable substances that would raise that pressure by acting upon the nervous centers and the unstriated muscular fibers and to administer them in the most advantageous manner. We chose to this end atropine and strychnine employed simultaneously. But how should they be given? On account of the frequent vomiting in seasickness, by which any ingested substance would be rejected and lost, on account also of the difficulty of absorption in a seasick stomach, where the chief osmotic current is flowing toward its cavity, and, lastly, on account of the action of the liver by which it arrests and transforms these and other alkaloids entering it from the stomach and bowels (Hegar, Schriff, Lautenbach, Jaques, Roger), it was necessary to choose some way of administration of these alkaloids other than that of the gastro-intestinal tract. The hypodermic method seemed to us the best, and it is in this manner that we always exhibit these substances in seasickness.

The dose of these agents by subcutaneous injection in a well-developed case of naupathia should be for adults from a half to one milligramme of atropine and one milligramme of strychnine dissolved in mint water. The following is the formula we employ the oftener:

Atropin. sulphat.	0.02 gramme;
Strychnin. sulphat.	0.04 “
Aquæ menth. pip.	40.00 grammes.

One gramme, or one cubic centimetre, of this solution contains half a milligramme of atropine and one milligramme of strychnine. In hot climates this solution loses a little of its strength at the end of a month, and it should therefore be frequently renewed when used in the tropics.

Although we have employed these active substances hundreds of times, we have not yet seen the least harmful result in adults. In regard to the distilled mint water that figures in the formula, we are unaware if it has an action that should be taken into account. It was selected on account of its more or less merited reputation of usefulness in seasickness. If in the space of two hours after the first injection the patient is not cured, a second injection of one gramme (or one cubic centimetre) of the solution may be injected, and even a third two hours later. But we esteem that it is not prudent to exceed this number of hypodermic injections per day in naupathia.

Children and adolescents are very susceptible to this medication. A child of two years and a half (Case III, see *Clinical Reports* at the end), sick during fourteen hours, was promptly and definitively cured by the injection of one sixth of a gramme of the solution—that is to say, by circa 0.00008 of atropine and 0.00016 of strychnine—a truly infinitesimal dose. A boy of six years was cured by the injection of a fourth of a gramme of the solution; another, eight years old, by half a gramme, which was somewhat too much for a lad of his age. (See Cases VI and VII.)

The effects of this medication are often surprising. In the majority of simple cases of seasickness the patients cease vomiting at once after having received a single injection of one cubic centimetre of the above solution. Soon afterward they feel no more nausea, cephalalgia, or distress. Only a few minutes are required for this result to be obtained. Occasionally two injections are necessary to produce complete euphoria.

Everybody knows what a pitiful spectacle a really very seasick person presents. He is painfully seated near the ship's rail or is lying down, caring not how or where, so long as he can vomit easily; he is pale, apathetic, vomiting, and suffering from headache and vertigo. But the injection of these alkaloids transforms this person in a little while. He ceases to groan, the vomiting stops, color returns to his cheek, and he affirms that he is "much better," or that he does not suffer any more at all. If the injection is given during the daytime he almost always falls asleep for half an hour or longer; if given in the evening, when the patient has retired for the night, the sleep is calm, prolonged, and restoring—so much so that when the physician visits his patients on the following morning he hears them assert with satisfaction that "the night was passed very well." This means a great deal to a person who has been kept awake a night or more by seasickness.

One of the best proofs of the efficacy and innocuousness of this method is found in the fact that patients ask for a repetition of the treatment, and mothers who have been treated have it done to their children.

There is another substance which we have employed in seasickness with good results, and that is caffeine given hypodermically.* It acts somewhat more slowly than the alkaloids just named, and its effect is less constant, but it is often efficacious, as the cases related below will show.

In our practice we used the formula of Tanret and Dujardin-Beaumetz, which is as follows:

Caffeinæ.....	4 grammes;
Sodii salicylat.....	3 "
Aq. dest.....	q. s. ad 10 c. c.

Dissolve by gentle heat. Each cubic centimetre contains 0.40 gramme (40 centigrammes) of caffeine. A single dose of 0.30 gramme injected subcutaneously cured a patient completely in seven hours who had been sick three days. (See Case XI.) In another case this dose cured in five hours in the same conditions.

A mixture of cocaine, caffeine, and atropine did not produce such good results as the mixture of atropine and strychnine.

Possible Objections to this Method.—The administration of such toxic substances as atropine and strychnine requires, of course, great attention and prudence on the part of the physician, and none but a physician should give these agents. He should carefully observe their action, and, above all, before injecting them he should accurately proportion the dose to the age and the constitution of each patient. Atropine ought not to be administered too often; once the proper dose exceeded, there follow depression and enfeeblement of the patient.

It was said above that we have never seen harmful effects due to these substances, given as directed. However, there are sometimes produced certain disagreeable effects, though they can hardly be said to be important. The most frequent of these effects is the dryness of the mouth and air passages due to the atropine. But the patients prefer this to being seasick. Children sometimes present a generalized redness of the skin due to the same drug which may cause parents some anxiety, but it soon disappears. Once we noted irregular pulse in a boy after a single injection (Case VI), but his general condition was so good, he laughed and played so naturally, that all idea of danger was rejected.

Atropine given even in a small dose in seasickness sometimes causes temporary amblyopia (Case V). In such cases the proportion of strychnine should be increased and a somewhat smaller quantity of the solution should be injected.

Not infrequently passengers that have been quite severely sick present a certain degree of prostration and an indisposition to make any muscular effort, even after they have been entirely cured of their naupathia by the injection of strychnine and atropine. They are certainly cured because they feel no more nausea, or vertigo, or distress, and they have no more vomiting, pallor, ptalism, etc. This state of languor, of reluctance to move, may last from six to twelve hours, seldom longer. It may be entirely due to the exhaustion which a severe attack of seasickness leaves after it, but it might possibly also be deepened by the action of the atropine absorbed. At all events, the termination of this state is always favorable.

The seat of the injection is not ordinarily painful. Rarely it leaves a painful spot after it, which is tender for a day or two, and very rarely it produces a redness and swelling quite annoying. But we have never observed an abscess

* W. W. Skinner. Treatment of Seasickness. *British Medical Journal*, October, 1886.

or phlegmon as a result of these injections. The inflammatory phenomena subside spontaneously and all is soon in order again. It should be remarked that these accidents are not disagreeable enough to prevent the patients from seeking the same treatment again as soon as they feel seasickness return.

The counter-indications of this method are quite rare. When the diagnosis has been correct we have never observed a case rendered worse in any respect by the exhibition of these substances, even when the patient had another disease coexisting with seasickness.

It happens from time to time that the injection of these two remedies does not cause any amelioration; the trouble continues in spite of all and lasts long. In these cases it is almost certain that the patient has one of those affections that were named among the predisposing causes of naupathia and which are, above all, affections of the circulatory apparatus, as has already been explained.

What is it that we mean by the cure of seasickness? Do we mean that as soon as the remedies are given the vomiting patient gets right up out of bed and promenades the deck as gayly as if in a ballroom? By no means. There is no power in the universe that could produce that result while the sea is still rolling high. But we do mean that the vomiting and even the nausea stop, that the splitting headache stops, that the patient is comfortable, that he or she generally falls asleep a little while, and that soon afterward food is relished and retained. The patient may still remain in bed, but he is not seasick, and it is not necessary to wait for still water before this result can be obtained. Can more than this, or as much as this, be said of any other method of treatment of seasickness?

Let it suffice to say, in conclusion, that the judicious employment of this method never does any serious harm; that it may very rarely be inoperative, owing to some cardiac, vascular, or nervous lesion; but that *in simple naupathia it always produces amelioration and generally a cure of this affection.*

(To be concluded.)

CURED CASES OF ATROPHIC RHINITIS.

By JOHN DUNN, M. D.,
RICHMOND, VA.

In August, 1893, Mrs. K., aged thirty-two years, came to consult me about her eyes. Examination of her nose revealed a condition of affairs I had for a long time wished to be able to say I had recognized beyond question. I have called it advisedly a cured case of atrophic rhinitis. The condition of the nasal cavities? At first glance one sees a mucous membrane whose color is perhaps a little paler than normal; the inferior turbinates appear shrunken—so contracted, as it were, that on the left side, in order to see the inferior turbinate at all, it is necessary to turn the patient's head much toward her shoulder; the middle turbinates are smaller than normal, while their inferior edges have lost to some extent their peculiar glazed, moist appearance and their regular curve. Further than this a hurried examination reveals nothing. "Doctor, I wish you would not say to me in the presence of my companion anything that would lead her to suspect that I once had *ozæna*." This remark made

me examine more closely the appearance of the nasal mucous membrane, and it quickly became apparent why this mucous membrane was "a little paler than normal," for it was the seat of numerous minute depressions—all small, some larger than others—irregularly placed; these depressions, now plainly visible as minute scars, had neither the healthy red color nor the moist appearance of the adjacent healthy areas of mucous membrane. And to what part of the nasal cavities were these scar areas confined? To no one part of it. They were spread promiscuously over the turbinates, septum, and floor of the nose, and were very plainly marked and larger than elsewhere near the posterior border of the septum. But, for all this, there was no visible sign of any present active inflammatory process. The inflammation had disappeared, was no more. The atrophic rhinitis was cured.

The scars were the visible signs of there having been present in the nose at some past time a very general and severe inflammation. Mrs. K. then told me that her "catarrh" began to be annoying when she was about eighteen years of age, from which time until she reached the age of twenty-eight it had been the bane of her existence. Nor had she been able to escape the horrid odor that accompanied the constant accumulations of scabs in her nose. For four years she has had practically no nose trouble whatever, no odor (and there was none present the times I examined the nose), no unusual nasal discharge. "My nose nowadays is not the cause of my soiling a pocket-handkerchief once a month." Nor is she annoyed by a sensation of undue dryness of the nasal cavities. In short, her nose is no longer the source of discomfort. The sense of smell did not return with the disappearance of the inflammation.

At the same time I had under my care Mr. M., aged twenty-six years, who for fifteen years has been a victim of atrophic rhinitis. In the light of the case of Mrs. K., I examined his nose carefully, to find here also that the scabs which accumulated along the floor of the nose were not there as the result of gravity, but were the result of an inflammatory process affecting the mucous membrane covering the floor of the nose; that the septal mucous membrane was a source of these scabs, especially that part of it situated near the posterior edge, where Zuckerkandl places the plicæ septi, and where we often enough find the so-called "ballooning of the septum," both of the false and true hypertrophic kind; and that, furthermore, they were numerous and hard to detach in the region of the pharyngeal tonsil; and, of course, numerous, continuous, thick, etc., over the turbinates. In short, the usual picture found in old cases of this trouble.

Let us now see how far this cured case, as I have termed it, bears out the teachings in regard to the origin, nature, and course of atrophic rhinitis. On this subject the first article to which I had recourse was that by Dr. John N. Mackenzie—*Cirrhotic (Atrophic) Rhinitis*, in Burnett's *System of Diseases of the Ear, Nose, and Throat* (1893). Under *Ætiology* there is "a classification of the stages of chronic nasal inflammation" into "simple inflammatory, hypertrophic, atrophic"; and in the concise explanation of these three stages all of the attention is turned to the condition of the erectile tissues of the nose, as though in them were to be sought the cause and sole places of development of this disease. No mention is made of the condition of the rest of the nasal mucous membranes. Under the next heading—that of Pathology and Pathological Anatomy—Dr. Mackenzie says: "The gross anatomical appearances of the first stage consist essentially in localized or diffuse injection,

with moderate swelling of the tissues. There is very little, if any, swelling of the mucous membrane proper, the *main condition being repeated engorgement of the erectile bodies.*" Then follows a description of the changes through hypertrophy and atrophy of the *erectile tissues*. In part second of this division Dr. Mackenzie mentions in a general way the changes the nasal mucous membrane undergoes, without any special reference to the membrane covering either the floor of the nose, the septum, or the postnasal space. Under Symptoms and Diagnosis no specific mention is made of the condition of the mucous membrane of the floor of the nose or of the septum. "The pathological history of 'ozæna' is, moreover, that of the conversion of hypertrophic changes into those of an atrophic form. In the rhinoscopic image, in the microscopic section, the processes of hypertrophy and atrophy are found side by side. More than that, the atrophic changes are more pronounced in situations in which the catarrhal inflammations originally developed."

"As the result of the repeated erection of the cavernous tissues, which occurs in the first stage, a paralytic or subparalytic state of the resilient and contractile elements of the walls of the erectile cells develops. . . . It is this subparalytic condition of the tissue which is the connecting link *between the simple and the hypertrophic stages.*"* We may admit all this as taking place, and evidences of such transformations from congestion to hypertrophy and thence to atrophy are to be seen not only in the cavernous tissue of the turbinates, but in the faucial and pharyngeal tonsils, and also, I believe, commonly enough in the drum membrane and conjunctiva. Hypertrophied tonsillar tissue atrophies by exactly the same process as do the turbinate bodies—by the formation of new connective tissue which in turn contracts. Nor is this process of hypertrophy and thence atrophy of the turbinate bodies confined to the period of life when atrophic catarrh holds sway. I remember to have removed from the inferior turbinate of a lady more than sixty years of age a *localized atrophy*, the result of a previous hypertrophic condition. More than this, these hypertrophic conditions of the turbinates may exist without there being any demonstrable affection of the general mucous membrane of the nose. These hypertrophic conditions may affect one part of the turbinate more than another; most frequently the dependent and posterior parts of the turbinates show its presence most markedly; or they may be present in the inferior and not in the middle turbinates. Hypertrophy of the turbinates may result from various causes, and may result in a more or less localized cirrhosis of the turbinate tissue; but that *per se* "repeated erection of the cavernous tissues" is ever the cause of "atrophic rhinitis" I can see no reason for believing. The fact that during the history of atrophic rhinitis the turbinate tissues show, under the microscope, evidences of a process resembling cirrhosis of the turbinates, does not prove that simple cirrhosis, "the result of repeated engorgement of the cavernous tissues," is the cause of atrophic rhinitis. Nor is the fact that, as the result of atrophic rhinitis, the changes most noticeable to the eye are to be found in the

turbinate tissues any reason for selecting these as the regions where the disease originates. Atrophic rhinitis causes marked changes, both gross and microscopic, in the turbinate bodies; but the same disease produces also marked changes in other parts of the nose where the erectile tissues are not, and hence it would seem to be the rational plan to describe at length the changes occurring in the simpler tissues and in those tissues that are common to all the nasal cavities, and from these changes to arrive at the nature of the disease process producing them.

"The histological picture is simply that of a gradual atrophy or wasting away of the different layers of the mucous membrane, and the conversion of their individual elements into fibrous connective tissue, a purely cirrhotic process." And this seems to sum up Dr. Mackenzie's teachings about the nature of "atrophic rhinitis." This is no explanation of the nature of "atrophic rhinitis," and contains nothing in any way satisfactory about the origin of the disease. It does not in any way differentiate "atrophic rhinitis" from any other form of rhinitis where, as a consequence of hypertrophy, atrophy follows; and yet "atrophic rhinitis" surely has characteristics sufficiently pronounced to claim at least one or two determining factors which do not belong to certain other forms of nasal hypertrophies.

"Repeated erection of the cavernous tissue"—Dr. Mackenzie's teaching as to the origin of "atrophic rhinitis"—will, so far as I have been able to see, never result in this disease. I have never seen a case where it seemed in any way likely that such was the sequence of events, while the numerous cases of chronic erection of the cavernous tissues—*e. g.*, where a septal spur or deviation acted as an exciting cause—show always a picture so different from anything seen in atrophic rhinitis that one is forced to the conclusion that alone "chronic erection of the cavernous tissues" can never cause "atrophic rhinitis." Further, I see no reason for finding in a "paralytic or subparalytic state of the resilient elements of the walls of the erectile cells" anything to represent the first stage of a process which runs amuck through such regions as the floor of the nose and the pharyngeal tonsil as well as through those regions blessed with cavernous tissue. We see frequently enough children who suffer for years from a practically continuous erection of more or less of the cavernous tissues of the nose, the result, in part, of the existence of hypertrophied naso-pharyngeal tonsil, who nevertheless attain their maturity without a trace developing of that abomination of desolation—atrophic catarrh.

Dr. Bosworth (*Diseases of the Nose and Throat*) believes that, "commencing in a desquamative inflammation of the nasal mucous membrane, there is set up the disease, purulent rhinitis, which constitutes the early stage" of atrophic catarrh, "that form of catarrhal inflammation of the nasal mucous membrane which, developing in the direction of glandular atrophy, leads eventually to a more or less complete destruction of the muciparous glands and follicles, together with a true cirrhotic condition of the mucosa proper, resulting in a condition of the nasal mucous lining in which the prominent and characteristic symptom consists in the

* Italics are Dr. Mackenzie's.

formation of crusts and scabs, which, lodging in the sinuous passages of the nose, undergo decomposition and become the source of a fœtid and offensive odor." "Begins as a desquamation of the epithelium from the surface of the mucous membrane." While the inflammation is confined to this "the discharge is thin and muco-purulent." "Naturally, however, the morbid process will not confine itself to the superficial layer of the membrane." "The glands become involved; then follows a loss of secreting power. The muco-purulent discharge assumes a more inspissated character, and, lodging upon the convex surfaces of the turbinated bodies, dries and forms a closely adhering film, clinging to the membrane in such a way as to interfere with the vascular circulation." And much of the further history of atrophic rhinitis is attributed by Dr. Bosworth to the repeated and continuous embraces of these dried scabs. While I believe with Dr. Bosworth that the fact that the secretions become inspissated and adhere to the diseased mucous membranes is in a measure responsible for many of the changes occurring later in the history of atrophic rhinitis, I can not agree with him in regard to the manner in which these changes are brought about. "The mechanical action of this dried film is not unlike that of collodion, for in drying it contracts and embraces the turbinate bones in a grasp which necessarily must interfere with the circulation of the blood in the venous sinuses." The crusts form. Why? Because of the changed nature of the secretions from the mucous membrane. The watery part of the secretions from the more diseased areas is deficient in quantity and the inspired air quickly extracts it all, leaving on the surface a dried film. As long as this film remains porous the inspired air continues to draw water for its own purposes from the secretions below. The film becomes thicker; there remains, however, beneath the film, which eventually becomes a crust, a certain amount of the secretions which never dry. Not only is the watery part of these secretions deficient, but there is a deficiency of the salts found in normal mucous secretions. There is thus lacking an element important for the separation of the mucoid elements from the surface of the diseased areas, from the mouths of the diseased glands. Witness how easily and thoroughly weak saline solutions cause the detachment of these scabs. Not only are the secretions deficient in water and the salts, but there would seem to be an increase in the mucin, or some mucoid substances excreted by these diseased areas; perhaps there is more or less fibrin in the secretions. Furthermore, the destruction of the mucous membrane with its glands results not only in a decrease of the relative amount of water secreted, but also the total amount is insufficient. The scabs form; their surfaces are drier the further they are from the mucous membrane beneath them. The injurious effects of these dried scabs are not to be sought in the compression they exert on the membrane beneath; for it seems to me this is the least of the evils that result from their continuous presence. Let us see for a moment some of the other conditions resulting from their presence. To a certain extent these scab shields furnish homes for the propagation of the microbial agents that in-

fest a diseased mucous membrane; their multiplication and the retention of the products of their destruction against the mucous membrane must, it would seem, be a factor in the continuance of the inflammatory condition already at work in the mucous membrane. Moreover, these scabs prevent the mucous glands from properly discharging their contents, offering as they do obstructions over the mouths of these glands. Again, the presence of these scabs does not allow in the mucous membrane beneath them that ceaseless activity which, in the normal nose, is called into play by the passage of air over its surface, which activity is necessary to the proper development and continuance in its normal state of the mucous membrane. These scabs in the above ways, then, tend to perpetuate the disease in the membrane over which they form far more than by the pressure they exert on the membranes beneath them.

Those who hold that atrophic rhinitis is one of the gifts of inheritance, placing it in line with rachitic and syphilitic teeth, interstitial keratitis, strumous glands, etc., have at first glance a strong case. "Grandmother and grandchild," "father and child," "brother and sister," are some of the coincidences, if you will, of our note-books. On the other hand, however, there are so many cases where atrophic rhinitis has not a single companion to champion its claim to heredity, the concomitant affections of the ear, eye, or throat being offsprings of its own existence, that we must look to other influences for our cause.

"Atrophic rhinitis" must have a beginning somewhere. Its existence as an affection at once of the turbinates, floor of the nose, septum, upper part of soft palate (part continuous with floor of the nose), pharyngeal-tonsil region, and, at times, invading other domains—lacrimal duct, etc.—would seem to show that it did not claim any tissue peculiar to one region of the nose as its point of origin. The nasal mucous membrane has an epithelial layer, an adenoid layer, and a connective-tissue layer. To Bosworth belongs the honor of first maintaining that atrophic rhinitis has its origin in early childhood in purulent rhinitis, and it would seem that this is its true origin. Beginning as a purulent affection of the nasal mucous membrane, at first the chief changes are shown in the epithelial layers; later on there results massing of lymphoid cells in the adenoid layer, and, as the prime cause of inflammation of the mucous membrane is not removed, eventually there results the development of new connective tissue in the adenoid layer—for the rest its distinctive effects produce, in the course of time, atrophic rhinitis. Atrophic rhinitis is the result of a chronic inflammation, originally purulent, of the nasal mucous membrane, the result of untreated purulent rhinitis of children. This purulent rhinitis is something more than a simple catarrhal affection, the result of congestion changes in the mucous membrane. Catarrhal rhinitis affects by far the larger per cent. of all children in this part of the world. Purulent rhinitis in children is comparatively rare. Bosworth says: "I know of no assignable cause for the disease (purulent rhinitis of children) other than taking cold" (*Diseases of the Nose and Throat*, vol. i, p. 157). I am not inclined to agree with Dr. Bosworth that "taking cold" is the cause of purulent rhinitis. I think rather that the pres-

ence of an infectious principle is a *sine qua non*. Purulent rhinitis is in many respects comparable to purulent conjunctivitis. Neglect this latter affection and it will do for the mucous tissues of the lid what purulent rhinitis does for those of the nose. The anatomical variations will account for the different pictures presented. Purulent conjunctivitis always receives more or less attention. Purulent rhinitis of children receives, in all but the most exceptional cases, what amounts to utter neglect; partly because it is a painless affection and causes no complaint on the part of the child; partly because the parents do not appreciate its gravity; and, in a very great part, because under all circumstances treatment is difficult to apply properly.

Although I have seen purulent rhinitis in the infant in arms, I have never had the opportunity of seeing this disease in its incipency. It has always already existed "weeks," "months," or "years" before the case has been brought to my attention. I do not, then, know the history of its beginning; but I can not believe its origin to be identical with the ordinary catarrhal rhinitis of children, for were this so "ozena" would be pre-eminently the most common disease of the Atlantic States.

The more I reflect on the case of Mrs. X., the more pleasing do I find certain of the lessons it seems to teach. In the first place, it allows us to say that some cases of atrophic rhinitis are eventually permanently cured. We learn from it that the inflammatory condition at the bottom of the whole trouble may disappear; that the formation of new connective tissue ceases after its disappearance; that the inciting cause to the formation of new connective tissue having been removed, that already formed behaves just as similar tissue does in any scar; nor are, then, the pleasing effects of time less apparent in the mucous membranes than in the outer skin. When the battle is once over and the enemy has retired from the field, it is wonderful to what extent the damage done is repaired. Where the inflammatory process has been severe enough to destroy, in part or whole, the cavernous tissues, it does not seem likely that Nature can regenerate them. The regenerative power of the mucous epithelium is well known, and it seems to me we are forced to admit that there is also a power of regeneration for those elements of the adenoid layer essential to the life of the epithelium on its surface—a power which asserts itself to the elimination of the new-formed connective tissue, the inflammatory cause having been removed.

Considering then atrophic rhinitis, as I do, the result of a definite inflammatory process of the nasal mucous membranes, which process, owing to the anatomical conditions existing in the nose, is capable, if proper treatment be not applied, of continuing itself indefinitely and of producing by the formation of new connective tissue the picture so well known to all rhinologists, the prognosis of this disease I am willing to view more favorably than many do. As long as scabs continue to form in the nose the inflammatory process must be considered to exist, the disease to be not cured. Of course, in speaking of cured atrophic rhinitis, I do not mean that the nose, then, has the power of perform-

ing all of its duties as well as a normal nose. Far from it. The inflammation has destroyed the olfactory nerve terminals, and the sense of smell is often completely abolished; the more or less complete destruction of the erectile tissues deprives the nose of more of its power to do work for the economy; the widening of the nasal air spaces has, too, its effects for change from the normal. In the face of all this, those cases from which the active inflammatory process, the cause of this disease, has disappeared, should be considered cured.

In regard to treatment I have nothing new to offer. The following method has, however, proved at my hands to be the most satisfactory I have as yet had any experience with. Like all other methods that have any value in the treatment of atrophic rhinitis, it requires patience and care on the part of the physician, and the assistance of the patient. The nose must be cleansed of all scabs and secretions. This part of the work must be most carefully done. We must remember that atrophic rhinitis is not essentially or primarily an affection of the nasal cavernous tissues, but that the mucous membrane of the floor of the nose; of the septum its whole extent, and especially near its posterior border medially; of the turbinates, inferior and ethmoidal; and of the region of the naso-pharyngeal tonsil—are all involved, and that the removal of the scabs clinging to the inferior border of the turbinates is not sufficient to cleanse the nose. The use of the spray I consider to be far from the most efficacious means of cleansing the nasal cavities. Preferable for this purpose are probes and cotton. The best and cheapest nasal probes with which I am acquainted are made from knitting needles. The sharp ends are cut off so as to render them blunt; the extremities of these blunt needles are then held over a gas flame for a minute so as to slightly roughen them, that the cotton when wrapped about the probe will not slip. For the purpose of cleansing the nose salt water is used—half a teaspoonful to a glass of tepid water. A wad of cotton as large as will pass easily into the entrance to the nose is wrapped about the end of the probe; this is dipped into the salt water, and passed through the speculum into the nose.

The nasal cavities should be thoroughly illuminated so that all of the work done can be seen. The contact of the wet cotton passing over the scabs suffices in most cases to detach them, so that in a few seconds all of the scabs are sufficiently loosened to allow the patient to blow them from the nose. Occasionally it happens, however, that here and there the secretions require for their removal a second or third application of the wet cotton, and also a little rubbing. With the use of this cotton wet with salt water the nose can in a very few seconds be cleansed of every particle of its secretions. When the mucous membrane is clean, the next step is to make an application of nitrate of silver (ten to forty grains to the ounce, according to the state of the mucous membrane) as far as possible to the whole of the diseased areas. This is applied in exactly the same manner as the salt solution. Naturally a part of the silver is neutralized by the salt water left in the nose. Enough, however, reaches the mu-

cous membrane to answer our purposes. Immediately following the application of the silver is another application of the salt solution in order to neutralize whatever of the silver there may remain (just as is done after silver applications to the conjunctiva). With the probe and cotton the whole of the diseased areas should next be washed with one-to-twelve-hundred bichloride-of-mercury solution, rubbing well with the cotton thus wet the areas where the scabs were thickest. Following this, the nasal cavities should be sprayed with some liquid alboline solution, generally the now well-known camphor-menthol one. When the patient is first seen this treatment is applied daily, then every other day, then twice a week, and at the end of about two months once a week. Generally the patient is pleased, in spite of the somewhat severe treatment, with the results. The patient's part of the treatment consists in washing out the nose night and morning with a weak salt solution, for the application of which he prefers a spray, and when the nose is as clean as he can get it, in applying some of the following salve:

R Anise oil..... ʒxx;
Beechwood creasote..... ʒxx;
Vaseline..... 3j.

M. Sig.: Nose salve.

The application of this is made by placing a small piece of the salve in one nostril; then, closing the other, the patient draws in his breath forcibly. This salve, although it reaches only a small portion of the diseased areas, proves, in many cases, very grateful to the patient. I do not profess to have obtained by this method any cures in cases of atrophic rhinitis. It has, however, given general satisfaction when it has been used, and so lessens the odor and the sensations of stuffiness and dryness about the nose as to render its use worthy of trial where one has not already a method which is as satisfactory as one knowing the nature of this disease could expect. It does produce marked changes in the condition of the nasal mucous membrane, and while it may not bring about within a given time a cure, it seems to assist Nature in its struggle to restore to the nose a lining which will perform the functions natural to this organ. Its use persisted in will, I believe, although I am unable to speak from results obtained, bring about eventually a condition of the nose described in the beginning of this article as found in the case of Mrs. X., and so allow us to speak with authority of "cured cases of atrophic rhinitis" the results of a definite method of treatment.

The University of Maryland a Sufferer by Fire.—On December 2d a disastrous fire visited the property of the university and completely destroyed Practice Hall. This building had recently been enlarged by the faculty. It had within its walls perhaps the best dissecting rooms and laboratories to be found in Baltimore. The old university building took fire, but fortunately the flames were extinguished before great damage was done. The losses are severe, but the buildings will without doubt be restored before another year comes round. The laboratory studies of the current term were not seriously interrupted, as the faculty was enabled to arrange for their continuance without delay.

THE HÆMOSTATIC VALUE OF PEROXIDE OF HYDROGEN.*

By GEORGE EMERSON BREWER, M.D.

It is only within the past five or six years that the attention of the medical profession has been directed toward the value of peroxide of hydrogen in surgery.

Since the publication by Dr. E. R. Squibb, of Brooklyn, of a paper in which he described the advantages of this fluid as a disinfecting and antiseptic agent, especially in diphtheria and other septic diseases of the upper air-passages, its value has become more generally appreciated and its use gradually more extended among those of the profession who have largely to deal with this class of diseases.

Regarding the hæmostatic action of this drug little has been said. Although it has been mentioned by several observers, and it has been generally accepted that, under certain circumstances, its use has often been accompanied by the evidences of feeble hæmostatic action, it has never been regarded as a reliable agent for this purpose.

On five or six occasions, however, during the past year, the use of peroxide of hydrogen in the hands of the writer has seemed to arrest hæmorrhages from nasal or throat operations which at the time proved quite annoying.

I will mention but two of these cases, as they will fairly represent all, and leave the members of the club to determine whether or no I am correct in attributing to the peroxide the virtue which resulted in the rapid relief:

CASE I.—A young lady, aged twenty-five years, applied for treatment of a catarrhal condition of the naso-pharynx accompanied by marked nasal obstruction.

Upon examination, a moderate-sized cartilaginous spur was found upon the anterior portion of the septum, projecting well into the cavity of the left nostril. After a certain amount of preliminary treatment this was removed by means of the nasal trephine. As the bleeding which followed seemed moderate, she was instructed to allow it to drop into a fixed basin arranged for the purpose. The bleeding, however, appeared to increase, and at the expiration of fifteen or twenty minutes no longer dropped, but seemed to flow in a minute stream. A plug of cotton wool was placed in the anterior nasal orifice, and the head tilted well forward in the hope that clotting would thereby be facilitated. This plug, however, was soon saturated, and seemed in no manner to arrest the flow of blood. A solution of aceto-tartrate of aluminum was next applied to the cut surface, but to no purpose. A firm cotton plug was then saturated with the solution, and considerable pressure exerted upon the wound, but without relief.

As the patient had then been bleeding about forty or fifty minutes, and was beginning to show evidences of loss of blood, an application of Monsel salt was made with marked pressure by forcing a conical cotton plug within the nostril. This seemed for a few minutes to arrest the flow of blood, but it soon found its way backward, and appeared in the mouth and right nostril.

As this method, in the experience of the writer, had never failed to arrest a similar hæmorrhage when the cut surface was accessible, it was thought that the pressure of the cotton could not be evenly adjusted; the plugging was therefore removed and the process repeated with even more care and with more

* Read before the Hospital Graduates' Club, October 26, 1898.

pressure. The hæmorrhage, however, in spite of this application, continued, and when it was finally demonstrated that no benefit was being derived, after an interval of from ten to fifteen minutes, everything was removed, the clots expelled, and the patient propped in a comfortable position and allowed to bleed without interference for several minutes, in the hope that the diminishing blood pressure would allow coagulation and result in the ultimate arrest of the hæmorrhage. This, however, did not occur, and as the patient (who, by the way, was throughout the entire operation most reasonable and free from nervous excitement) began to experience feelings of giddiness, became extremely pale and somewhat exhausted, preparations were made to plug the posterior nares. With a view to cleansing the nasal cavity before applying the posterior plug, I applied on a cotton swab a fifteen-volume solution of peroxide of hydrogen, and was pleased to note an immediate cessation of the hæmorrhage, which did not recur.

CASE II.—The patient, a man, aged thirty-two years, suffering from marked enlargement of the tonsils, was told that the removal of both glands would, in all probability, be followed by prompt relief. Accordingly, one was removed on May 26th by means of the Mackenzie amygdalotome. The wound promptly healed with but insignificant loss of blood. Five days later the other was removed in the same manner, and, as the resulting hæmorrhage was slight, the patient left the office for his home within three quarters of an hour from the operation.

As he had been accustomed to making applications to the throat for several years, and possessed a considerable amount of skill with the applicator, he was told, in the event of hæmorrhage, to apply strong peroxide of hydrogen to the bleeding surface. Three or four hours later I was hastily summoned to his house by the report that the bleeding had been considerable. As soon as I entered the patient's room it was clearly evident, from the blood-stained towels and utensils which were scattered about, that he had experienced a considerable loss of blood. The patient exhibited marked pallor and was extremely weak. The pulse was small and rapid.

On examining the throat, however, I saw a large, firm clot, and no evidences of present loss of blood. He explained to me that the hæmorrhage had started shortly after leaving the office, had gradually become more profuse, and was not controlled by applications of ice or by astringent sprays. As soon as he was able to procure the peroxide of hydrogen and arrange his lights and mirror, he had made the application as directed, and it had been followed by a prompt cessation of the bleeding. That the hæmorrhage had been extensive was evidenced by the fact that during my visit he vomited a large amount of clotted blood, and twice during the night which followed, when he attempted to rise from his bed, he fainted and fell to the floor. The hæmorrhage, however, did not recur.

As in several other instances in the writer's experience equally satisfactory results have followed the use of this agent under similar conditions, it has been thought advisable to call attention to its possible hemostatic action, and, although I am not prepared to say at present that the arrest of the hæmorrhage in any of the cases did not result from the lowering of the blood pressure, or from some other favoring circumstance, still it seems to me to be worthy of a more extended trial.

To explain the hæmostatic action of this drug, the theory has been suggested that the rapid clotting of the blood was due in great measure to the fact that the peroxide-of-hydrogen fluid when brought into contact with organic matter is rapidly decomposed, giving off free nascent oxy-

gen. This, by uniting with the hæmoglobin, converts the blood, which is generally venous in character and charged with carbon dioxide, into bright arterial blood, which it is well known is much more readily coagulable than the vitiated fluid.

I was, however, led to question the correctness of this theory when I observed that in some of my most alarming cases the bleeding was distinctly arterial in character, and that these cases seemed to yield to the treatment as readily as those in which the oozing was undoubtedly venous.

I am indebted to Dr. William G. Thompson, professor of physiology in the Medical Department of the University of the city of New York, for some facts which he observed during a series of experiments with this agent (as yet unpublished) which he has recently been conducting at the physiological laboratory of that institution.

He observed that when a strong solution of peroxide of hydrogen (fifteen volumes or more) was brought into contact with the blood by being directly injected into the veins during life, it caused a rapid disintegration of the red corpuscles, resulting in the immediate precipitation of a semisolid detritus which completely occluded the smaller vessels; that this effect extended so rapidly throughout the vascular system that within a comparatively short space of time the animal operated on would present the appearances characteristic of the most profound anæmia.

He also observed that the application of strong solutions of this agent to mucous and serous membranes caused an almost immediate degeneration of the epithelial cells, resembling at first a rapid and exaggerated cloudy swelling, and later a complete destruction of the tissue.

In view of these facts, the writer is inclined to believe that the arrest of hæmorrhage which is observed when strong peroxide of hydrogen is applied to a freshly wounded surface results from this remarkable disintegrating action both on the tissues and the blood, rather than the simple oxygenation and rapid coagulation of the latter, for it is easy to understand how the rapid swelling of the endothelial lining of the cut blood-vessels and the solidification of the blood within them would result in a more or less complete obliteration of their lumen.

REPORT OF SEVEN CASES OF TETANY.*

By BERNARD E. VAUGHAN, M.D.

TETANY is a disease quite common in some parts of Europe, but rare in this country. Osler, in his text-book, states that in the discussion of a case presented by Dr. Stewart at the Association of American Physicians at Washington, 1889, Dr. Weir Mitchell had seen but two cases and Dr. Pepper but one, and that in a child.

The disease is characterized by tonic spasms affecting the extremities. The ætiology is in doubt. Von Jaksch, who has described an epidemic among young men of the working classes, in some cases accompanied with slight fever, regards the disease as infectious; this form is acute

* Read before the Hospital Graduates' Club, April 20, 1893.

and rarely fatal. It often accompanies rickets, chronic diarrhoeas, the acute fevers, and lactation, and Trousseau has called it nurses' contracture. It has occurred in cases after the removal of the thyroid gland, and in dilatation of the stomach, particularly after lavage. In fact, the nature of the disease is unknown, but it probably depends upon the action of some toxic agent on the motor cells.

Symptoms.—In some cases there is fever; it has been reported as high as 104° F., but in mild cases the symptoms are chiefly those of tonic spasm of the extremities. The hand is drawn into a position suitable for holding a pen. Trousseau has described it as the "accoucheur hand." It is best understood if you remember the muscles supplied by the ulnar in the hand—namely, the *interossei*, two of the *lumbricales*, muscles of the little finger, and the adductor and part of the *flexor brevis pollicis*. Consequently you get flexion of the metacarpo-phalangeal joints and extension of the second and third phalanges; the inner side of the hand is drawn inward; the thumb is strongly adducted and flexed. The wrist is flexed, also the elbow, and the arms are drawn toward the chest. In the lower extremities the toes are flexed and the feet are in the position of talipes equinus. Rarely it extends to the muscles of the face and trunk. These contractions are intermittent or more or less persistent. Pressure on nerves produces the spasms, and there is increased electrical reaction of the muscles.

The diagnosis of the case is quite easy; it must be distinguished from hysteria and from trismus. The former is unilateral, while tetany is bilateral. In trismus the jaw is first affected, while in tetany it begins in the extremities. For treatment, bromides, baths, massage, and electricity have been used.

For the cases I have to report I am indebted to Dr. Ginnasi, physician to the afternoon Italian class of the New York Dispensary. Five of these cases occurred in one family, and it may be of interest if I describe briefly the place in which they lived:

It was a rear house, never receiving direct sunlight; four steps below the ground; ceiling about six feet and a half high; room eight by ten feet, with two small windows; in the rear, another room, five by eight feet, having no windows. On the other side were two similar rooms—and in this place lived two families of twelve persons.

CASE I.—V. M., aged thirty-five years, female, nursing child five months old. Three months ago began to have formications in feet, extending up the back, neck, and head, and then into the hands. In about a week she began to have contractions, limited to the upper extremities. She had some pain in the abdomen and constipation. The contractions would last about an hour, and occurred three or four times daily. This continued up to a few days ago, when she came to the dispensary. The position of the upper extremities was exactly as described. We put a pen in her hand and she would hold it indefinitely, and was not able to relax her grip. Eight grains of quinine, three times a day, were given, and the contractions were relieved in eighteen hours, but the muscles felt sore and painful. In a week from the last visit the patient returned to the dispensary with a relapse, but the contractions were not as typical or as persistent. The feet were slightly affected, which

interfered with walking. On the following day Dr. Walter Vought and I made careful tests of the electrical reactions of the muscles. They were all increased in both cathodal closing and anodal opening. In some cases the smallest amount of current that we could measure—namely, an eighth of a milliampère—was sufficient to produce distinct muscular contraction. In all cases the reaction occurred with half the amount of current required in a normal subject; also the anodal opening was greater than the anodal closing contraction.

CASE II.—M., aged fourteen years, daughter of V. M. Menstruation just established. She began to have contractions two weeks later than her mother, preceded by formications; were less severe, but more continuous, relaxation only occurring once or twice a week, when the patient could move her fingers for about two hours; then the contractions would recur. Position of hands and arms typical.

CASE III.—M. M., girl, aged three years. Began to have cramps in the upper extremities at the same time as her mother, but spasms have occurred only twice a week.

CASE IV.—N. M., aged twelve years. Has menstruated. Two months ago she began, as the others, with formications, cramps in stomach, and constipation; contractions in her case were very continuous. Position of upper extremities typical. Pressure on brachial plexus increased the contractions. Four grains of quinine, three times a day, were given; contractions disappeared in a few days. She complains of soreness in the muscles and pain in her tongue and left eye.

CASE V.—Aged thirty-three years, married, nursing a child two months old. Lives in opposite basement. Three weeks ago she began to feel formications in her feet, extending up the back to the head and then in the arms. Contractions began two days ago, when I saw her at the dispensary. Pressure on brachial plexus increased the contractions. Eight grains of quinine, three times a day, were prescribed. After sixteen grains had been taken the contractions ceased and have not returned. Pressure on the brachial plexus causes a feeling of formication in the arm. Both in this case and in Case IV the temperature was 100° F.

CASE VI.—Teresa, aged twenty-five years, married, two children, youngest eleven months old, nursing. Lives in a dark, damp basement. The patient is anemic and poorly nourished; looks very sick. Temperature, 104° F. Pulse, 108. Spleen slightly enlarged. Three days ago she began to have formications, beginning in the feet and extending as the others. Began four days ago to have contractions in the hands and came to the dispensary. Position not quite typical; could move the fingers. Pressure on the brachial plexus increased the spasms, which were more like the others. The following day I saw her at her home, and contractions had ceased after quinine. Temperature, 101° F.; pulse, 100. Pressure on brachial plexus caused pain.

CASE VII.—Vincenzo. Reported to me by Dr. Ginnasi. Works on docks. Had typical spasms in both hands and feet.

Besides these cases reported, quite a number have been treated in the New York Dispensary in the morning Italian class. It has seemed to me that such a rare disease ought to be reported, and I wish to call attention to these facts: That five in one family suffered with the disease; that three cases were in nursing women, two in girls who had just begun to menstruate, one in a rickety child, and one in a male adult working in a damp place, and all of these subjected to the worst possible hygienic surroundings. Then there was the rapid disappearance of the symptoms under

the influence of quinine, the use of which is not mentioned in the text-books. All these facts, I think, point toward the infectious character of the disease.

A CASE OF
COMPLETE GLOTTIC SPASM IN AN ADULT,
FOLLOWED BY
UNCONSCIOUSNESS AND PROLONGED DROWSINESS.*

By W. PEYRE PORCHER, M. D.,
CHARLESTON, S. C.

As I have been able to find records of only twenty-seven cases of laryngeal vertigo or complete glottic spasm in adults, and on account of marked implication of the brain centers, as shown by torpidity of bowels, persistent drowsiness, and other symptoms which are novel, at least to the writer, I have ventured to make the following brief report of this case:

The patient was a maiden lady, aged fifty-two years, at the menopause. She was brought to my office for the supposed removal of large tonsils on account of difficult respiration at night, with frequent terrifying nightmares. She attributed this condition to an attack of grippe which she had had several months before. Since that time the paroxysm had not been severe, but her attendants stated that she would be awakened by the cough after dropping to sleep, and it was described by her as a feeling of choking or gagging in the throat. There was no dyscrasia, except such as resulted from a slight malarial cachexia. She was of a very sanguineous temperament, inclined to plethora, and so nervous that she expressed the greatest alarm when requested to enter my dark room. She could not go into a church or other crowded place without a sense of fear and oppression.

On examination, her tonsils were found to be so small that they could not be caught in the grasp of either of two improved amygdalotomes. They were therefore thoroughly cauterized with the galvano-caustic knife.

She was ordered a simple antiseptic gargle of listerine and water, and cautioned against taking any hot food, coffee, etc.

The first night after the operation she had no great pain or unusual difficulty of breathing. The next morning she attempted to drink some coffee which she said was not hot. Upon taking the first teaspoonful she complained of a peculiar giddiness and rushed to the window for air, but fell back upon the floor unconscious. The attack lasted but a short time. On my arrival soon after, she had entirely regained consciousness and was comfortable. As her attendants stated that she was very drowsy, ten grains each of calomel and soda were ordered to be taken at once. At the evening visit it was found that the medicine had not acted, and the next morning there had been but one slight evacuation. This, together with the persistent drowsiness, which lasted for several weeks, indicated that there was marked implication of the brain centers, although there has been no return of the attacks of insensibility.

She was ordered sulphate of strychnine, a twentieth of a grain, with a grain each of quinine and iron. This dose was gradually increased until a tenth of a grain of strychnine was taken three times daily. Small doses of a saline cathartic were also given from time to time in order to keep the bowels open.

About thirteen days after the first cauterization, the left

tonsil remaining still somewhat enlarged, a second application of the galvanic electrode was made to it. This was followed by most satisfactory results. She informed me that her rest the night following had been very refreshing, without difficult respiration, pain, or nightmares.

The patient was kept under observation for about fifteen days longer. At the end of this time she expressed herself as having regained control of her nerves and considered herself well.

On account of the well-known tendency of hot coffee to enter the larynx, and for the reason that I know of no other exciting cause to which to attribute the sudden attack of insensibility, and as there were no signs of paralysis, I have been inclined to regard this as a case of laryngeal vertigo or complete glottic spasm, and have so entitled it. It might be thought that the vertigo was in some way due to the menopause, but this would not account either for the prolonged stupor or the torpidity of the bowels. Cases of laryngeal vertigo have been reported in which cough has either been absent or not of any great severity, and others in which the nervous element was most prominent, but in which there were no attacks of absolute insensibility, and again other cases in which very slight paroxysms of cough would be followed by complete unconsciousness. The insensibility with slight cough, as in this instance, is perhaps best explained by McBride's theory that the attack was preceded by a series of short inspirations followed by spasmodic expiration and a partially closed glottis. Here, also, the patient was not even aware that any coffee had actually entered the larynx, but was seized with a sudden gasping for breath, and, after rushing to the window, fell unconscious, as she said, "in a heap upon the floor." It is the opinion of the writer that this loss of consciousness, like aural vertigo, is a symptom of a specific disease, and should not be confused with that vertigo which results from holding the breath for a sufficient length of time, or even that which results from a severe paroxysm of cough or sneezing. It should not in any respect be regarded as an epilepsy, as there was never any spasm or jerking of any description at the incipency or at any time during the attack.

REMARKS ON
CONGENITAL DEFECTS OF THE FACE,
WITH EXHIBITION OF A RARE FORM OF CLEFT PALATE.*

By HARRISON ALLEN, M. D.,
PHILADELPHIA.

I HAVE here a skull, and in connection with it a drawing, which illustrates a rare form of congenital defect. The specimen is the skull of a Seminole Indian taken from the Morton Collection in the Philadelphia Academy of Natural Sciences. The collection is for the most part made for ethnological purposes, and this particular skull shows evidences of having been exposed to fire, which probably indicates a pre-Columbian burial rite.

The defect in the palate is directly in the median line.

* Read before the American Laryngological Association at its fifteenth annual congress.

* Read before the American Laryngological Association at its fifteenth annual congress.

In other words, it is not the form of cleft palate which is generally described. The cleft palate which we know of from the books is the result of the failure in the descent of the fronto-nasal process to reach a level with the other bones of the face which are developing from the sides. There may either be one or two fissures, resulting in double or single cleft palate. The rudiments of the incisor teeth lie between the clefts. This specimen is so far different that on the right side there are distinct sockets for the incisors. On the left side the sockets for the incisors are absent. We have evidence that the cleft in the roof of the mouth itself is distinctly in the median line. On turning the specimen, so as to get a front view, it will be seen that the maxillæ descend unequally, the one on the left side being carried down further than the one on the right. There is a disproportion between the two sides of the face. It will also be seen that the septum is exceedingly irregular, one of the nasal chambers (namely, the left) being much narrowed. The septum is deflected in a remarkable manner, so as to form a gross deviation to the left.

The right nasal chamber is intact. The individual suffered only on the left side from the result of the cleft. Here is a large fissure opening from beneath, and the left nasal chamber is freely continuous with the mouth. It is evident, from the appearance of the teeth, which have been subjected to full use, that these peculiarities did not interfere with the individual's masticating powers. The spur formed by the union of the perpendicular plate of the ethmoid bone with the vomer is deflected so far to the left that it has formed an adventitious depression for its reception in the left middle turbinal bone. I wish to dwell upon this point, for I have long been of the opinion that many forms of nasal headache, catarrh, and distress are due to similar pressure effects. I know that some of the fellows of this association do not accept this thesis, but I think that a study of the specimen will help strengthen the position I have taken. It is difficult to see how this spur could avoid making sufficient pressure on the turbinated bone to excite distress. This is certainly true of patients who have an irritable nervous system, and it might have been true here. In my experience, when the middle turbinated bone is cauterized, particularly on the side, it creates a hygroscopic eschar which becomes thick the day after the operation and produces headaches. These are relieved only on the removal of the eschar.

When the subject of the ætiology of deviations of the nasal septum was first studied they were attributed almost entirely to injuries. I remember when I first read a communication on this subject before the Philadelphia Medical Society, there was no one present who agreed with me that such deviations were due to other causes than traumatism. It is difficult to prove that they are not due to traumatism, because few children escape blows on the face. The history of a blow is all that is needed. I acknowledge that it is exceedingly difficult to make the contrary proposition good, but I have been inclined of late years (perhaps because my experience with these cases has been an exceptional one) to the opinion that deviations of the nasal septum are very rarely traumatic; that they are almost

always congenital and, like most congenital conditions, are associated with a disposition to minor defects in more than a single direction. Ordinarily, indeed, the entire region of the face, including the superimposed frontal bone and the roof of the mouth, exhibits peculiarities which correlate with nasal conditions. I endeavored to establish this proposition many years ago, but practitioners are indifferent to data of this kind.

Examining the specimen for details, we find that the middle turbinated bone is of enormous size on the right side, while on the left side it is a mere wafer-like scale. These bones show no evidence of being peculiar from behind, while in front they present marked asymmetry. This illustrates the law that all structures grow in the line of least resistance.

TWO CASES OF SUPERNUMERARY NIPPLES, WITH REMARKS.

By L. E. DIONNE, M. D.,
NORTH BROOKFIELD, MASS.

THE case of supernumerary nipple reported by Dr. Albert Pick in the *New York Medical Journal*, October 28th, reminds me of two cases observed in my own practice.

L. J., a well-developed German girl, presented a nipple in the right axilla.

S. D., a delicate woman, aged twenty-two years, was the bearer of a nipple situated about two inches and a half to the right of the right normal nipple. S. D. gave birth to a perfect child. Lactal secretion in normal nipples only.

Regarding the significance of that phenomenon, Darwin concludes that, "on the whole, we may well doubt if additional mammae would ever have been developed in both sexes of mankind had not their early progenitors been provided with more than a single pair."

Professor Leichtenstern says: "With Darwin we explain the accessory mammae and mamillae in man to be a reaction in the course of the evolution of man, standing in relation to our enormously distant ancestors of lower organization, who had more than two mammae, and adjudge every human being the latent capability or inclination to produce more than two breasts. This inclination, resting upon inheritance from our ancestors, has, however, been reduced, in the course of millions of years, to latency, but not to such a degree as has been generally assumed, as it has been proved that accessory and rudimentary mammae and mamillae occur much more frequently than has been formerly thought."

The views of the learned professor are particularly misleading, as they are said to be based upon modern embryology, and, like all other theories having a scientific aspect, have been accepted by many as ultima.

Fortunately for our peace of mind, they will not bear the force of careful observation and sound judgment.

From careful examination of the records of cases of accessory mammae and mamillae we learn that extra nipples are as accidental in their position as they are in their occurrence, that they do not occur more frequently than the other deformities found in the human race, and that

consequently they can not be of any greater significance than a simple malformation.

If it were reasonable to infer from their presence, would it not be as wise to infer from their site? Again, would it not be equally just to draw inference from other anomalies—accessory fingers, ear, etc.? Hence the absurd possibility of having for “enormously distant ancestors” beings with mammary glands and nipples in the axilla and having double hands ornamented by triple thumbs.

The lower animals give examples of monstrosity which are just as good material for inference as the deformations met with in both sexes of mankind. Who has not been urged to give a dime to see a two-headed calf, a hairless horse, etc.?

I remember seeing a four-year-old cow which had a foot on the middle of the back, and a horn about five inches long aside of it. It never occurred to my mind that that cow's great-grandmother was one of that kind.

The presence of an extra part of an animal body can not bear more significance than the absence of a normal part. Both conditions are monstrosities—the former monstrosities by excess (*monstra abundantia*), and the latter monstrosities by defect (*monstra deficientia*).

The cause of accessory nipples, etc., might be to science, as well as to supposition, a puzzling puzzle did we not remember the admirable work of the cellular system of our organization; but when we consider the behavior of these minute organisms, the cells, which are indefatigably laboring at the construction and repair of our body, have we not good right to look upon deformation (by excess) as the production of a bundle of wandering cells which, though exiled from their congeners, nevertheless accomplish their wonderful constructive object?

Notwithstanding modern embryology and other ologies, which often tend to debase the primary origin of mankind, we can not consider the morbid alteration of a given being as a *rapprochement* to his remote progenitors.

The scriptural genesis of man implies that we are of Adam and that Adam was of God. It is certainly safer and more important to believe that than to plunge into a doubtful past “millions of years” of which we have no history for the purpose of establishing relationship with a four-footed something having a full row of mammae on each side of the median line and acquiring the “latent capability or inclination” of transmitting the same to future generations, with the addition of a caudal appendix, as atavism may decree.

Who will dare to reflect upon the physical and intellectual superiority of man over all beings and say that he is not what he was intended to be on the morning of creation—the *chef-d'œuvre* of the Divine Architect—for “*quod est ultimum in actu est primum in conceptu*”?

A Serious Hospital Fire in Syracuse.—The Woman's and Child's Hospital, of Syracuse, took fire on December 18th from a defective flue. The patients were all got out in safety, but not without grave peril, since the weather was very cold at the time of their removal. The fire damaged the building to the extent of nearly \$4,000. A large proportion of the furnishings of the hospital were saved. The losses are well covered by insurance.

FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, DECEMBER 23, 1893.

THE GROWING POPULARITY OF ETHER ANÆSTHESIA IN LONDON.

THE *Medical Press and Circular* has had a series of reports on the anæsthetic procedures in several hospitals of London. King's College Hospital and the Royal Free Hospital are not free users of ether; the former relies on chloroform in a majority of cases, while the latter is partial to the A. C. E. mixture. In the case of nine other hospitals, the anæsthetists administer ether in the larger proportion of cases. At the London Hospital a very notable change has taken place in this regard; ether is the anæsthetic chiefly used, being administered twice as frequently as chloroform. A few years ago the opposite preference ruled, but a careful and extensive study of the relative workings of the two substances has effected this reversal. The anæsthetist of St. George's Hospital shuns the use of chloroform “unless there is some good and sufficient reason to give the coroner in case of a catastrophe,” although he considers the substance safe in the hands of a competent operator. Ether is by far the most popular anæsthetic at the Charing Cross Hospital, being used in seventy per cent. of the cases. Chloroform has the preference in operations upon the mouth, tongue, etc., or where the use of ether is contraindicated by the existence of some pulmonary complication. Dr. Hewitt, at the London Hospital, prefers chloroform in cases where bronchitis or emphysema exists, and a majority of the anæsthetists use it for children, elderly persons, and those who have bronchial trouble. Dr. Bourns, of the Westminster Hospital, however, does not refrain from the use of ether for old persons, since he thinks that apprehension with regard to the ill effects of ether in age has been excessive, and that when lung disease has followed etherization it is more likely to have been caused by some exposure of the chest or some faulty step in the operation than to have been excited by the vapor of ether. Nearly all the outpatient departments use nitrous oxide, and so do the anæsthetists of the hospitals when minor operations are performed. In some of the hospitals that substance is also used to induce a condition preliminary to full anæsthesia, the experience being that less ether is needed and a quieter and prompter sleep is obtained than when ether is used from the outset. In some cases chloroform is substituted for ether, if the patient under ether evinces a tendency to vomiting or bronchial irritation; after the ether has been withheld for a while it may be administered again. At St. Mary's Hospital ether is used first in patients that are badly nourished and run down from excesses; when the period of excitement has been reached chloroform is given instead of ether; afterward, when the patient is quiet and breathing regularly, the use of ether may be resumed.

The A. C. E. mixture mentioned above, although it has a London origin, has a better reputation in the United States than abroad. The proportions of the mixture are, by measure, alcohol one part, chloroform two parts, and ether three parts, its constituents to be of the best quality. This combination was used by Dr. Harley for several years in a quiet way, but in 1864 a committee of the Royal Medico-chirurgical Society gave it prominent mention in their report on anæsthetics.

The majority of London anæsthetists are particular to use the ether in as fresh a condition as possible, and preference is given to the use of an inhaler. The Clover inhaler is largely used, though Ormsby's and Junker's have their adherents. Apparently much less ether is used for a patient in London than for one in our own hospitals.

THE NEW YORK STATE LUNACY COMMISSION.

For some time there has been apprehension lest the Lunacy Commissioners of this State should fall from the grace and honor of their office by undue exercise of the despotic power with which they have been invested by the Legislature, and by the insatiable desire and greed for more power begotten of the privileges already given them. No particular fault is found with the commissioners themselves, except that they do not stand upon the same plane as some of their predecessors, like Ordranax, who administered the functions of the office in such a way as to bring distinction to himself and glory to the Commonwealth.

The object of the creation of such an office as that of commissioner in lunacy was to provide for the regular inspection of public and private asylums for the insane. In England the need for such an officer originally arose in connection with the abuses of private asylums, to which occasionally sane persons were sent, and in which at times patients were unduly detained and restrained. Such a government inspector should see the patients, talk with those that have complaints to make, investigate charges of abuse, diminish mechanical restraint, and note whether inmates are properly fed, clothed, and exercised. He should aid and abet in every way the asylum superintendent's natural desire to improve the institution under his care, and to ameliorate the condition of the unfortunates committed to his charge. Beyond such duties and the minor details pertaining to the same, the Commission in Lunacy should have no other prerogatives, and indeed we doubt if a properly constituted commission would desire more.

The evils which are now arousing a storm of protest in the daily papers all over the State and in some of the medical journals are wholly due to the extraordinary powers granted to the present commission, and to the meddlesome and oppressive manner in which such powers are wielded. As is well known, the hospitals for the insane of this State are foremost among institutions of the kind in this country. Their superintendents are medical men pre-eminent in their special calling, understanding more clearly the needs of the asylums and better able to provide for the welfare and happiness of their charges than

the commissioners. In addition to a medical superintendent and his corps of medical assistants, each asylum has a board of managers selected from among the best citizens in every part of the State, whose duty it is to co-operate with the superintendent in managing all the affairs of the institution. These citizens are gentlemen of high standing in their respective communities, and fortunately, owing to the time-honored custom of their being appointed by Governor without party distinction, few if any of them are politicians. It is needless to say that the State hospitals for the insane, as thus constituted, have been in all respects creditably managed, and no meddlesome interference in the management should ever have been permitted. As already intimated, such interference has been instituted by the commissioners in lunacy, apparently to gratify an insatiable ambition, and the tendency seems to be toward the creation of a huge political machine at Albany having control of all the purchases of supplies, of appropriations for new buildings, and after a time of the appointment of superintendents, stewards, medical assistants, nurses, and attendants. The commission has already absolute authority as regards each minute expenditure in every asylum of the State, so that not even a lead pencil can be purchased without the consent of this centralized body. The cutting down of necessary appropriations for blankets, clothing, fuel, food, tobacco, and the like has been the immediate cause of the indignation everywhere aroused. Now, instead of a commission to look to the welfare of the insane, we have a body whose only purpose apparently is to make political capital out of the cry of economy. The tendency is down hill. It is toward demoralization of the whole scheme of State charity. It is against the interests of the insane. It will place the State care of the insane on the so-called "economical" level of the County House.

While we have nothing personal against any member of the present commission, we believe that the inherent human instinct to grasp for more power, manifested so decidedly in this instance, should be curbed. We believe the law should be so changed as not to stimulate and develop this instinct. The Massachusetts people are congratulating themselves at the present moment that the same plan for centralizing power as to details of management of State hospitals was overwhelmingly defeated in their legislature, and are commiserating us on account of the mode of enforcement of bad law, which enforcement is worse than the law itself. Every reform and improvement in the care of the insane in this State has had its inception in the State Board of Charities, the State Charities Aid Association, and former commissioners in lunacy. Much that the present commission has undertaken has been for the purpose of self-aggrandizement and to serve political interests. It is rather obstructive of legislation, looking toward the real interests of the afflicted people whom they were originally intended to protect. It has been said that the true reason of the veto of the epileptic-colony bill last winter was the influence of the Commissioner in Lunacy upon the Governor, for the law establishing said colony placed it in the charge of the State Board of Charities, and not in the hands of a body itching for

further extension of its executive powers in the State. We sincerely trust that a legislative remedy will soon be sought for this state of things, and that the Commission in Lunacy will hereafter be charged only with its legitimate supervising and advisory functions.

MINOR PARAGRAPHS.

THE NEW JERSEY MOSQUITO IN LONDON.

ACCORDING to *Insect Life*, the scientific periodicals of this country have omitted to notice the fact that the genuine mosquito from the Hackensack flats finds its way to England, although the newspapers have occasionally made mention of the fact. The above-named journal states that it can confirm the rumor. It says: "A large and voracious species of *Culex*, indistinguishable casually from the species common about New York harbor, is to be found in London, and is not infrequent in the large hotels. They were particularly bad in 1886 at the Grosvenor Hotel, Victoria Station, and proved even more annoying to the Londoner than to the many American guests of the hotel. These insects are undoubtedly being carried over occasionally in the large ocean steamers, and the gradual reduction in the length of time of the voyage will undoubtedly result in an increase of such instances. A recent number of the *London Spectator* mentions the fact that in a large colliery in the north of England the men at work in a distant part of the mine complained that the galleries were full of mosquitoes. As ordinarily it takes something worse than a mosquito to frighten a collier, the manager went down to explore, and found large yellow-banded wasps in great abundance."

TOBACCO AND THE DIPLOCOCCUS PNEUMONIE.

TOBACCO, under certain conditions, seems to be antagonistic to the coccus of pneumonia. Dr. Welch has shown at the laboratory of the Johns Hopkins Hospital, says the *Journal of the American Medical Association*, that the action of tobacco smoke on bacteria, as the smoke is drawn through the culture tube, is inhibitory. There was formerly a medical worker in his laboratory who had always in his buccal secretions the *Diplococcus pneumoniae*, and who was able to supply the other workers with samples for cultures. But after a time this physician began to chew tobacco, and no more cultures could be got from his saliva, for the tobacco had exterminated the micro-organism.

A MECHANICAL MEANS OF TREATING WHOOPING-COUGH, TRIGEMINAL NEURALGIA, ETC.

THE *Centralblatt für klinische Medizin* for December 9th mentions an expedient described by Dr. Naegely, in the *Mercure médical*, 1893, No. 31, for cutting short the paroxysms of whooping-cough and for the treatment of trigeminal neuralgia, hemicrania, globus hystericus, and nervous vomiting. It consists in seizing the two greater cornua of the hyoid bone with both thumbs and holding the bone, together with the larynx, up for from sixty to ninety seconds. The efficacy of this manipulation is said to have been proved in a sufficient number of cases. The author can not explain its *modus operandi*, but he is inclined to think that it calls an inhibitory reflex into play.

QUOUSQUE TANDEM?

Is there any limit to the effrontery of the "enterprising" pharmaceutical manufacturers? Certainly in the case of some of them there does not seem to be. The latest example of vul-

gar assurance on their part is the issue of a hideous calendar, every sheet of which bears an assertion of the superiority of a certain product, surmounted by the portrait of some well-known physician. It is to be presumed that most of these portraits, if not all of them, are put to this low use without the consent of the persons they represent, and probably without the formality of their having been consulted in the matter. At all events, we are glad to have been assured by one of the gentlemen on whom this indignity has been put that he has taken legal proceedings against the offending concern.

THE TREATMENT OF MALARIAL DISEASE IN CHILDREN.

In the *Revue générale de clinique et de thérapeutique* for December 2d brief mention is made of a book on new methods of treating malarial fever in children, by Dr. Moncorvo, of Rio de Janeiro. It seems that the author, in imitation of Maninoff, has tried a tincture of the leaves and flowers of *Helianthus annuus* with good results. He has used methylene-blue also, but it is not easy to estimate the degree of his success with this drug, for the amazing statement is made in the *Revue's* abstract that thirty-six patients were treated, of whom ten were cured and thirty-nine benefited! It is much to be regretted that errors of this sort are very common in the periodical literature of medicine.

THE GAZETTE MÉDICALE DE PARIS.

THE issue of the *Gazette* for December 2d presents an improved typographical appearance, and it is announced that Dr. Pierre Sebilean succeeds Dr. F. de Ranse as the editor. The new editor states that the last page of each number will be devoted to matters of special interest to students who intend to try the *concours* for the *internat*, such as knotty questions in anatomy, physiology, and pathology that may be asked by the examiners. In the number before us nearly two pages are given up to such a treatment of the anatomy and physiology of the velum palati.

ITEMS, ETC.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 10 to December 16, 1893:

KULP, JOHN S., First Lieutenant and Assistant Surgeon, now on temporary duty at Jackson Park, Chicago, Ill., is relieved from further duty at Columbus Barracks, Ohio, and when his services are no longer needed with the troops at Jackson Park will report in person to the commanding officer, Fort Sheridan, Illinois, for duty at that post.

BREWER, MADISON M., First Lieutenant and Assistant Surgeon, having relinquished the unexpired portion of his sick leave of absence, will report in person to the commanding officer, Fort Monroe, Virginia, for temporary duty at that post.

GIBARD, ALFRED C., Major and Surgeon, is granted leave of absence for four months, to take effect about January 6, 1894, with permission to go beyond sea.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending December 16, 1893:

SIEGFRIED, C. A., Surgeon. Detached from the U. S. Training-ship Richmond and granted four months' leave.

HAWKE, J. A., Surgeon. Detached from Widows Island Hospital and ordered to special duty at Portsmouth, N. H., and to the U. S. Training-ship Richmond.

SIMONS, M. H., Surgeon. Ordered to Widows Island Hospital and to special duty at Portsmouth, N. H.

DEAN, R. C., Medical Director. Ordered as President of the Board of Medical Examiners, Washington, D. C.

HOEHLING, A. A., Medical Director. Detached from the Board of Medical Examiners and to wait orders.

BRADLEY, MICHAEL, Medical Director. Relieved as President of the Board of Medical Examiners and ordered as member of the board.

Marine-Hospital Service.—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Four Weeks ending December 16, 1893:*

BAILHACHE, P. H., Surgeon. Granted leave of absence for five days. November 28, 1893. To inspect quarantine ports. December 7, 1893.

PURVIANCE, GEORGE, Surgeon. To inspect quarantine ports. December 7, 1893.

SAWTELLE, H. W., Surgeon. To inspect quarantine ports. December 7, 1893. Granted leave of absence for three days. December 4, 1893.

AUSTIN, H. W., Surgeon. Detailed as chairman of the board to amend and revise quarantine regulations. December 9, 1893.

GASSAWAY, J. M., Surgeon. To proceed to Mobile, Ala., as inspector. November 22, 1893. To inspect quarantine ports. December 7, 1893.

MEAD, F. W., Surgeon. Detailed as chairman of the board to examine candidates, Revenue-Marine Service. December 9, 1893.

CAETER, H. R., Surgeon. To proceed to Brunswick, Ga., for temporary duty. November 29, 1893. To inspect quarantine ports. December 7, 1893. Detailed as member of the board to revise and amend quarantine regulations. December 9, 1893.

WHEELER, W. A., Surgeon. Detailed as member of the board to revise and amend quarantine regulations. December 9, 1893.

BANKS, C. E., Passed Assistant Surgeon. Granted leave of absence for seven days. November 22, 1893.

CARMICHAEL, D. A., Passed Assistant Surgeon. To inspect quarantine ports. December 7, 1893.

WHITE, J. H., Passed Assistant Surgeon. To proceed to Savannah, Ga., for duty. December 4, 1893. Detailed as member of the board to revise and amend quarantine regulations. December 9, 1893.

CARRINGTON, P. M., Passed Assistant Surgeon. To proceed to Baltimore, Md., for duty. December 9, 1893.

WILLIAMS, L. L., Passed Assistant Surgeon. To proceed to Charleston, S. C., for duty. December 4, 1893.

PETTUS, W. J., Passed Assistant Surgeon. Granted leave of absence for eleven days. To proceed to Buffalo, N. Y., for duty. December 4, 1893.

KINTOUN, J. J., Passed Assistant Surgeon. To rejoin station, Washington, D. C. November 24, 1893. Granted leave of absence for three days. December 4, 1893. Detailed as recorder of the board to revise and amend quarantine regulations. December 9, 1893.

WOODWARD, R. M., Passed Assistant Surgeon. Granted leave of absence for seven days. To proceed to Cairo, Ill., for duty. December 4, 1893.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed as recorder of the board for the physical examination of candidates, Revenue-Marine Service. December 9, 1893.

COBB, J. O., Passed Assistant Surgeon. To inspect quarantine ports. December 7, 1893.

GUITÉRAS, G. M., Passed Assistant Surgeon. To report at bureau for temporary duty. December 6, 1893.

GEDDINGS, H. D., Passed Assistant Surgeon. To proceed to New York for duty. December 2, 1893.

YOUNG, G. B., Assistant Surgeon. To proceed to New York for duty. December 4, 1893.

STIMPSON, W. G., Assistant Surgeon. To proceed to Detroit, Mich. December 4, 1893.

BROWN, B. W., Assistant Surgeon. Granted leave of absence for seven days. To proceed to Washington, D. C. December 4, 1893.

HOUGHTON, E. R., Assistant Surgeon. To proceed to Vineyard Haven, Mass., for duty. December 4, 1893.

ROSENAT, M. J., Assistant Surgeon. To proceed to St. Louis Mo., for duty. December 4, 1893.

NYDEGGER, J. A., Assistant Surgeon. Granted leave of absence for seven days. To rejoin station, Pittsburgh, Pa. December 7, 1893.

STEWART, W. J., Assistant Surgeon. Granted leave of absence for fourteen days. November 27, 1893.

STRAYER, EDGAR, Assistant Surgeon. Granted leave of absence for seven days. November 27, 1893.

OAKLEY, J. H., Assistant Surgeon. To proceed to Halifax, Nova Scotia, for temporary duty. November 24, 1893. To proceed to New York for temporary duty. December 14, 1893. To proceed to San Francisco, Cal., for duty. December 16, 1893.

Society Meetings for the Coming Week:

MONDAY, *December 25th*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, *December 26th*: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Medical Society of the County of Lewis (quarterly), N. Y.; Buffalo Obstetrical Society.

WEDNESDAY, *December 27th*: American Microscopical Society of the City of New York; New York Pathological Society; New York Surgical Society; Metropolitan Medical Society (private); Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.

THURSDAY, *December 28th*: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Proceedings of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of December 5, 1893.

The President, DR. M. ALLEN STARR, in the Chair.

Scleroderma.—Dr. L. STIEGLITZ presented a man, aged twenty-four years, who three years before had become affected with a swelling in the right submaxillary region. This had disappeared in about three weeks and had been replaced by atrophic tissue, and scleroderma had developed. About six months before the meeting the patient had begun to suffer from spasmodic contractions of the right masseter and platysma muscles, which still continued. The speaker did not believe

that the scleroderma and the spasmodic muscular contractions had been due to a common cause, although that was possible. He was rather inclined to think that the contractions were due to reflex irritation.

Gliosarcoma of the Basal Ganglia.—Dr. FREDERICK PETERSON presented a specimen from a man, aged fifty years, who had been in excellent health, with the exception of occasional attacks of vertigo and slight headache, until June 8, 1893, when he had fallen to the floor in his office. He had had a general convulsion and had been unconscious for ten hours. At the end of two weeks he had been well enough to return to his office from his home in New Jersey and to continue at work for five days, when headache and malaise had kept him at home. Four weeks after his first convulsion he had had five or six more of short duration and rather left-sided in character. At this time there had been left hemiparesis and hemianesthesia, also left hemianopsia with a tendency to somnolence; the pupils were equal and small; he was sometimes delirious, and had great frontal headache. His pulse was from fifty-two to sixty a minute; the respirations were slow and there was slight optic neuritis. The diagnosis of sarcoma or glioma, situated deep in the brain so as to affect the posterior limb of the right internal capsule, had been made. An operation had been out of the question. The man had been unconscious during the last three days of life. At the autopsy, made just five months after the first apparent onset of symptoms, a gliosarcoma had been found, about two inches in diameter, occupying the region of the basal ganglia, especially posteriorly, and projecting upward into the right lateral ventricle and downward somewhat into the right crus. It had not been strictly demarcated, and there had been some infiltration into the white matter of the brain, with here and there areas of softened brain tissue. A secondary tumor of the size of an almond had been found attached to the dura on the right side, compressing the cortex in the region of the angular gyrus.

Infantile Cerebral Spastic Diplegia.—Dr. PETERSON presented also the fresh brain of a female infant, aged twenty months, that had had congenital diplegia (spastic paralysis of all four extremities). The child had been subject to convulsions, and had enormously exaggerated knee-jerks and ankle clonus. Its head had been exceedingly small. At the autopsy the skull bones had been found to be considerably thickened and all the sutures and fontanelles closed and united. The dura was very thick. There was no increased amount of subdural fluid. Over each hemisphere a large group of convolutions, including especially the motor area, had been found wanting. The vacuum caused by this atrophy had been filled partly by subdural fluid and partly by the bulging of each ventricle; there had been no internal hydrocephalus and no communication between the ventricles and the exterior of the hemispheres. A microscopical examination of the spinal cord had shown degeneration and atrophy in the lateral columns.

Chronic Hydrocephalus without a Cerebrum.—This specimen also was presented by Dr. PETERSON. The case had been one of a female infant, aged eighteen months. Little could be learned of its early history. It had had a large head with widely gaping fontanelles. The child had been blind and had had nystagmus. There had been rigidity of all four extremities, occasional convulsions (the convulsions, Dr. Peterson said, he had not personally observed), and toward the last opisthotonus. The child had often cried out at night. Speaking to it or moving it had caused it to cry out. The pulse had been rapid and feeble. The lungs had been normal. The urine had contained a trace of albumin, but there had been no trouble with the bladder or rectal sphincters. The child could not nurse and had been fed with a dropper. It had died suddenly

in a convulsion. The temperature had never risen above 98° F. while the child had been under observation. Toward the last it had vomited occasionally after being fed. At the autopsy sixty-four ounces of reddish serum had first been removed by tapping at the anterior fontanelle. The skull was very thin, also the dura. The falx cerebri had disappeared. At the base of the brain there stood out prominently the basal ganglia and the floors of the lateral ventricles widely open. The cerebellum had appeared to be of normal size. There had been a mere vestige of each hemisphere. There had been degeneration and atrophy of the lateral columns of the cord.

Subacute Unilateral Bulbar Palsy.—Dr. ALFRED WIENER reported the case of a lad aged seventeen years. His family history had been negative with respect to any hereditary nervous trouble. He had always been in good health up to two years before, when he had been taken down with an attack of perityphlitis, from which he had recovered after five weeks of illness. In the spring of 1891 the glands on both sides of his neck, in the region of the sterno-cleido-mastoid muscles, had begun to enlarge. In the summer of the following year an abscess had formed in one of these glands and had had to be opened. In August, 1892, the glands on the right side, together with a large portion of the sterno-cleido-mastoid muscle, had been excised. Those on the left side had been removed the following month and had been found to be of a tubercular nature. The patient had recovered rapidly and nothing had been noticed in the way of any disturbance of the parts which might have been involved in the operation. In November, 1892, it had been discovered that the patient's tongue deviated to the right side, and shortly after this he had experienced some difficulty in swallowing. He had soon become hoarse and coughed with difficulty, and within a space of ten days there had developed a complete unilateral palsy of the right side of his tongue, the soft palate, the pharynx, and the right recurrent laryngeal nerve. There had been no disturbance of his respiratory or cardiac organs, and no other conditions present which would have called attention to an affection of any other cranial or spinal nerves, except the ninth, tenth, eleventh, and twelfth. The symptoms had remained stationary for a time; then the patient had begun to grow very much weaker, and suddenly, on March 26, 1893, had had an attack of respiratory failure. From this he had partially recovered, and then had continued in a condition of slight respiratory difficulty. He had been hardly able to speak above a whisper, and had had excessive salivation. On April 11th he could barely protrude his tongue beyond the edge of his teeth. His lips had remained normal and could be brought into perfect apposition. The palate and pharynx on the left side had remained normal. On April 20th he had had another attack of respiratory failure which had proved fatal.

The autopsy, made six hours after death, had revealed that the motor cortex, internal capsule, crura cerebri, and pons were normal. The nucleus of the twelfth nerve on the right side was much diseased, while on the left side it was diseased to a slight degree. The nuclei of the ninth, tenth, and eleventh nerves were slightly affected, a little more on the right side than on the left. The respiratory bundle appeared to be completely degenerated on the right side, while on the left, in the region of the hypoglossal nucleus, its lower and anterior portions were diseased. In the region of the ninth nerve a few fibers were affected. The intramedullary remains of the ninth, vagus, the vago-accessorius, and the hypoglossal nerves were less prominent on the right side than on the left. Otherwise everything had appeared to be perfectly normal up to the exit of the first cervical nerve in the spinal cord. As regarded the nature of the lesion, no tubercle had been found, as had been expected,

and no tubercle bacilli had been found on microscopical examination. There had been simply an atrophy of the ganglion cells and fibers motor in function.

From a careful consideration of the preceding case and the autopsy, Dr. Wiener had drawn the following conclusions:

1. The region of the hypoglossal nucleus gives origin to nerve fibers which supply the tongue, palate, pharynx, and larynx on one side of the body.

2. The column of nerve fibers known as the respiratory bundle consists of fibers from the glosso-pharyngeal, vagus, and vago-accessorius nerves, and the lower and anterior portion of this column probably serves as the locality for the vagus and vago-accessorius fibers.

3. The glosso-pharyngeal nerve seems to control the reflexes of nausea and gagging in the soft palate and pharynx, and also to send some of the motor filaments to the pharyngeal muscles. These latter filaments have their origin in the hypoglossal nucleus, ascend in the respiratory column to the nucleus proper, and then make their exit with the glosso-pharyngeal nerve.

4. The soft-palate muscles are not innervated by fibers from the seventh nerve.

The Pons-medulla Flocculus Triangle as a Tumor Site, with Pathological Findings.—Dr. ROBERT SAFFORD NEWTON

read a paper on this subject, which he illustrated by the following case: A woman, aged twenty-eight years, had entered St. Mary's Hospital on July 10, 1893, complaining of a constant headache for a fortnight, with morning vomiting and sickness for seven days. There had been no history of any trauma and no specific history. The family history had been negative. Two days after admission she had been examined, and, apart from "a silly manner and a slight drawing in her speech, she had presented no symptoms. On July 20th the patient had become weak and had fallen to the floor. She had muttered to herself during the night and moaned about her head. The pain had appeared to be diffuse. She had been dull and stupid and her speech had been prolonged and tedious. At this time there had been no defect of the cranial nerves. The pulse was forty-five a minute. She had a shuffling walk, with some tendency to go to the right. The superficial reflexes were present and the knee-jerk was increased on the right side. On July 22d the patient had become quite deaf and the headache was very violent, keeping her awake. On July 24th she had become very feeble, with marked deafness, especially in the left ear, but there had been no tenderness or discharge. The patient had stated that she could not see well, but the ophthalmoscope had shown no marked lesions. Upon standing up, she had been projected to the right very forcibly. The movement at each trial had been accompanied by a look of fear, paling of the face, dilatation of the pupils, and bathing of the surface in cold perspiration.

From that time on the patient had failed rapidly; The sight had become worse, and she had grown petulant and childish, but her appetite had remained fairly good. Nystagmus had been present for one day only. The external rectus had also been temporarily affected, and she had had a transient facial tic. The sense of smell had been present to the last. Optic neuritis had first appeared in the right eye, then in the left, and had rapidly gone on to total blindness. She had also become totally deaf. Her sense of taste was not appreciably affected, although she had occasionally complained of a hot, scalding feeling in the back of the tongue and in the palate. Her pulse had been slow from the beginning, and toward the last it had dropped to as low as ten, twelve, and fourteen beats a minute, and three days before her death it had dropped to six beats a minute. There had been no anæsthesia or implication of the

pain sense, temperature sense, tactile sense, or muscular sense. She had never had any convulsive seizures or paralytic attacks. The weakness had steadily progressed and there had been loss of control of the sphincters; the respirations had become slow and gradually ceased. Just before her death she had still been able to distinguish between whisky and milk.

The autopsy had been made ten hours after death. Upon removing the brain an enormous tumor with a central projection had been found on the left side. The swelling was somewhat triangular, and its apex was under the thalamus and geniculate body, its base crowding the cerebellum off from the medulla, and its side line not quite reaching the middle of the pons. In the central pons region there was a projecting mass shaped like a thumb. The bulk of the growth was a cyst. The left half of the pons was much softened and the medulla and cerebellum were flattened. The olfactory nerve was intact. The optic nerve was swollen on the left side, but the third and fourth nerves were intact. The fifth and sixth also seemed to have remained unchanged. The seventh nerve was on one side of the growth and the eighth on the other. The nuclei of the ninth, tenth, and eleventh nerves had been pushed aside by the change in position of the floor of the medulla. The nucleus of the twelfth nerve had been entangled in the growth. The cyst had begun at the margin of the fourth ventricle by a blocking of the channel of communication between the lateral cisternæ of the ventricle and the cavity of the arachnoid.

In concluding his paper Dr. Newton referred to the natural spaces or reservoirs of the subarachnoid fluid that existed in this portion of the brain, and to how easily a cystic growth might be developed there, also to what an enormous size it might attain and what numerous tissues and parts might be invaded without necessarily giving rise to any localizing symptoms.

Myelosyringosis; Central Glioma of the Spinal Cord, with Spontaneous Central Hæmorrhage.—Dr. CHARLES L. DANA

read a paper in which he narrated the history of the following case: The patient had been a man who had had a central gliomatous tumor in the lower part of the dorsal region of the spinal cord. This tumor had progressed slowly for two or three years, causing during that time the symptoms of a transverse myelitis chiefly, although the presence of a spinal tumor had been suspected. Among other symptoms there had been anæsthesia of the right side extending up to the twelfth dorsal spine and involving touch, temperature, and pain sensations. Anæsthesia had involved the left leg to a lesser extent. Just before the man's death a large hæmorrhage had occurred, which had been confined to the center of the spinal cord and which had caused exquisite pain, the man, in fact, having died from exhaustion. Upon post-mortem examination, a large central hæmorrhage, which had destroyed nearly every particle of the spinal cord at the level of the seventh dorsal segment, had been found. This hæmorrhage had extended up and down for a distance of about three inches. Around the hæmorrhage and above it there were evidences of a gliomatous infiltration involving nearly the whole of the transverse area of the cord at that level. Very striking secondary degenerations, ascending and descending, had been found. The case had been one of glioma of the spinal cord, without any cavity having been formed. Although clinically, and in one sense pathologically, it might have been a case of myelosyringosis, yet that name could not strictly be applied to it.

Commenting on this case, Dr. Dana referred to the question of the existence or non-existence of a pain tract and to the advisability of searching for it. The psychologists seemed to have come to the conclusion that pain was not a sensation, but a form of feeling; that it was not to be classed with the sensa-

tions of touch, or of temperature, or of heat; that it did not have peripheral end organs, and that there were no nerves in existence which, on irritation, produced pain alone; that there was no such thing as a pain tract; that in attempting to locate such a tract we were pursuing a will-o'-the-wisp. Dr. Dana said that after a very careful study of this question he had been converted to the psychologists' view. If we maintained that there was a special tract for pain, we could just as well maintain that there was one for hunger and one for each of various other sensations. If there was a special tract for any of the common subjective sensations, there must be a special tract for each.

Dr. B. SACHS said that in former days he had held to the view that pain was nothing more than an intensification of the ordinary tactile sense, and in the majority of cases we met with such an explanation would hold good, and under such conditions we should not look for any special pain tracts. The clinical facts that had been brought out with regard to myelosingosis, however, did not bear out that theory. The touch and temperature senses might remain normal, whereas the pain sense was entirely lost. The psychologists' view of this question was one that was rather difficult to reconcile with the clinical facts as to myelosingosis. On the other hand, this disease was very destructive and irregular in its course, and for this reason was rather an unsafe guide for us to go by in trying to determine physiological functions.

Dr. C. A. HERTER said that several years before he had hemisected the spinal cord of a monkey in the mid-dorsal region, and had been unable to find in that case any evidence of a loss of sensibility to pain, either on the same side as the lesion or on the opposite side. He had also performed this experiment on an opossum with a like result. Mott, in his experiments, had cut the antero-lateral ascending tract and had been unable to find any evidence of loss of sensibility to pain. The results of experiments on animals, of course, could not be applied directly to man. The subject brought up by Dr. Dana was an interesting one, and up to the present time we had not enough cases on hand to base any definite conclusions upon.

Dr. LANDON CARTER GRAY said that in our present state of knowledge as regarded the exact functions of the various columns of the cord—the column of Burdach, that of Goll, and the so-called column of Gowers—and the uncertainty that existed as to the exact demarcation of the latter, we could arrive at no definite conclusions as to the situation of the pain tracts. So far as clinical evidence went, there certainly was such a thing as a pain sense. In hysteria the tactile sense might be preserved, while the pain sense was entirely lost.

The PRESIDENT said we must admit the existence of pain sensations and of a centripetal pain tract. That tract must necessarily go in through the posterior nerve roots, because there were painful sensations of an hallucinatory character in locomotor ataxia. It must extend for a distance in the central gray matter of the cord. We had now on record over seventy cases of myelosingosis with autopsies. In these cases there was a decided loss of the pain sense in a certain limb. If the affected limb was the arm, the cavity in the cord was in the cervical region, and the pain sense was preserved in the body and legs. Therefore these sensations, though they entered the gray matter, did not pass up for any long distance in it, but must pass into the white columns. The central gray matter contained numerous cells, each of which sent its fibers into the antero-lateral columns, and these passed upward. While it was by no means positive that the antero-lateral columns transmitted sensations of pain, all the facts seemed to point to the correctness of that theory. The column of Lissauer, to which one of the speakers had referred, could have nothing to do with the trans-

mission of pain sensations. It consisted only of short fibers which did not increase in size from below upward and could not transmit impulses upward for any great distance. The sense of hunger was by no means analogous to the sense of pain, as Dr. Dana had intimated. We must distinguish between a common sensation and a special sensation. In conclusion, the president referred to a case reported by Edinger, with autopsy, in which the lesion had been found in the parietal region on one side, and in which the symptoms had been chiefly those of intense pain radiating in the opposite side of the body. Edinger had described it as a case of central lesion producing a sense of pain.

Dr. DANA said that his views regarding the non-existence of a pain tract had been arrived at only after a long and thorough study of the subject. When we had come to mix up pain sense, touch sense, heat sense, etc., we were showing a mental confusion that was unworthy of advanced neurologists. Pain and touch were entirely different. Pain was a subjective or common sensation. Touch was objective. Pain was much more closely allied to hunger than it was to touch. Pain was not a special sensation, but a modification of it. We might have a painful wound, but we did not have a simple sensation of pain; it was always combined with something else. If we could get rid of the idea that we must keep on hunting for a pain tract, it would save much exertion and many futile experiments on monkeys and men.

Book Notices.

Human Embryology. By CHARLES SEDGWICK MINOT, Professor of Histology and Human Embryology, Harvard Medical School, Boston. Four Hundred and Sixty Illustrations. New York: William Wood & Co., 1892. Pp. xxiii-815.

THIS is one of the most valuable and important medical books ever published in the United States, and one of the most notable text-books of embryology ever published in any country. It is founded on the author's original investigations and upon his thorough knowledge of what has been done in this field by others. The introductory chapter deals with the uterus and the development of the placenta and the fetal envelopes, together with a general outline of the development of the human fetus. Part I, entitled *The Genital Products*, is made up of chapter iii, devoted to the history of the gonoblast and the theory of sex. Part II, including chapters iv, v, vi, and vii, deals with the segmentation of the ovum, the primitive streak, the mesoderm, the celome, and the germ layers in general. The author discards the terms *epiblast*, *mesoblast*, and *hypoblast*, and remarks that, "as a thorough knowledge of German is indispensable to the student of embryology, it is justifiable, where no English equivalent is to be found, to adopt such unaltered German terms as have been fully established in embryological literature." He has acted accordingly. From one point of view this course serves a useful purpose, for it leads him to explain the meaning that various writers attach to terms of their own invention. For example, on page 329, under the description of the human chorion, we find this passage: "The fibrillar layer is that commonly spoken of as the connective-tissue layer of the chorion; for details of its structure, including the '*Gefassschicht*,' see Langhans and Kastschenko. The inner layer . . . is called the *Gallertschicht* by many German writers, and seems to be what Kölliker . . . designates as '*Gallertgewebe zwischen Chorion und Amnion*.'"

Surely, however, such terms as epiblast, mesoblast, and hypoblast have met with sufficient currency to warrant their retention in preference to certain German words made up of vernacular components the intelligible translation of which is at least a matter of difficulty, as is exemplified in the author's translation of His's term *Deckplatte* into "deck-plate." We are unable to see, also, that the German *Vorderdarm*, has any advantage over the English foregut, and we must positively disapprove of the substitution of the German *Anlage* for rudiment, especially since, as is to be seen on page 487, it is held to call for such an utterly un-German plural as "*Anlagen*."

Part III, including chapters viii, ix, x, xi, xii, and xiii, deals with the medullary groove, the notochord, and the neurenteric canals, the divisions of the ectoderm, the origin of the mesenchyma, of the blood, of the blood-vessels, of the heart, and of the urogenital system, the archenteron and the gill clefts, the germinal area, and the embryo and its appendages. Part IV, including four chapters, is devoted to the chorion, the amnion and proamnion, the yolk sac, allantois and umbilical cord, and the placenta. Part V, comprising twelve chapters, and almost half of the book, treats of the development and growth of the various parts of the fetus.

Although the book is so largely founded on the author's original investigations, he so far divests himself of even a semblance of egotism as to speak of his own published contributions on embryology with such an introductory clause as "Minot says." He specifically says in the preface: "Whenever I have inserted a new observation or opinion, it is indicated as such by the use of the first person." The courtesy which is invariably displayed toward other writers is remarkable and most creditable. It is well illustrated in the following paragraph on page 641: "The ganglion of the trochlearis was discovered independently by A. Frioriep, . . . and Julia B. Platt . . . in elasmobranchs. It is a part of the neural crest, and is continuous for a time with the anlage of the trigeminal ganglion; the connected band of cells breaks down irregularly, but its scattered remnants persist for a time along the original line. At this stage the motor fibers grow out from the medulla near the dorsal summit of the ganglion, and the permanent trochlearis is developed. Miss Platt speaks of the ganglion as the 'primitive trochlearis,' and she interprets, page 97, *ramus ophthalmicus superficialis trigemini* as a survival of the original connection between the trigeminal and trochlear ganglia. As the connection here mentioned is on the level of the dorsal line of the neuron, it may be regarded as a part of a lateral line commissure. The discovery of the ganglion of the fourth nerve further demonstrates that the motor fibers represent a lateral root. In torpedoid embryos of sixteen millimetres Frioriep (*loc. cit.*, 56) has found a small group of ganglion cells, which soon disappear, but at this stage are appended to the caudal side of the midbrain. These cells are probably a remnant of the original ganglion. Miss Platt thinks that the trochlear ganglion also contributes to the ciliary ganglion, but her proof of this appears unsatisfactory to me." He adds in a footnote: "Miss Platt's description is somewhat obscure by her overlooking the fundamental difference between medullary and ganglionic nerves." This footnote shows how telling criticism can be couched in courteous language. Even criticisms that savor of complaint the author succeeds quite as well in expressing without carping or injurious words, as is shown in the following passage on page 78, under the heading of the nature of sexuality: "Minot's hypothesis is strictly morphological and offers us no insight at present into the physiological aspects of sexuality. It has been adopted by Balfour and Ed. Van Beneden, neither of whom cite [*sic*] Minot." The only instance that we have observed in which anything approaching

discourteous dissent from an author's views occurs in the book is in a footnote on page 149, in which the author states that Mitsukuri has "attempted to deny" the views advanced by him. By the way, if Mitsukuri "attempted" to deny Minot's views, we can not see why he should not have succeeded; what the author probably meant to say was that Mitsukuri had attempted to refute his views.

The author's critical study of the literature of embryology is well exemplified in the following passage from page 300: "Coste's embryo has been beautifully figured in his great work. . . . It is possible that it really belongs to an older stage with the dorsal bend, compared to Fig. 169, and that it was stretched out by Coste; the difficulty of assigning it to its place is due to the entire uncertainty as to its actual dimensions. Coste's private collection is, I believe, now in the College of France, but upon search this particular specimen could not be found, so that His's inquiries to ascertain its actual length were resultless. Kölliker states that it was 4.4 millimetres long, but his authority for the statement is not given; the measure was probably taken from Coste's figure, '*grandeur naturelle*.' Since embryos of this length are far more developed than Coste's, it is probable that Coste's data as to the magnification of his figures are inaccurate. If we assume the embryo to have been really about 2.5 millimetres, it will then agree, except as to the great length of the rump, very closely with what we know otherwise of such young embryos."

There is no question of the author's thorough knowledge of his subject, and in general his style of writing is so clear as to stamp him as an excellent teacher. We find some slips, however. For example, the tense requirements of protasis and apodosis have been overlooked in a few instances; on page 1 the *mucosa corporis uteri*—correctly printed on page 3—is given as *mucosa corpus uteri*; on page 758 we find "cecum" for cæcum—a mistake that the author would probably never have made had he accustomed himself to the Roman pronunciation of Latin; on page 8 Allen Thomson's name is spelled Thompson; on page 178 we find "metecephalon" for metencephalon, and in the expression "foramen of Monro" the Scotch anatomist's name figures variously as "Munroe," "Monroe," and (correctly) Monro.

The volume presents a handsome typographical appearance, marred only by the bold-faced numerals indicating the dates and sequence of articles in periodicals. The pictorial illustrations are profuse, they answer their purpose well, and in general they are very well executed.

We feel sure that the faults to which we have called attention are the result of oversight, and we have mentioned them chiefly to aid in their correction in a second edition, which we hope will soon be called for.

A Text-book of Physiological Chemistry. By OLOF HAMMARSTEN, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Second Swedish Edition and from the Author's enlarged and revised German Edition. By JOHN A. MANDEL, Assistant to the Chair of Chemistry, etc., in the Bellevue Hospital Medical College and in the College of the City of New York. New York: John Wiley & Sons, 1893. Pp. x-511. [Price, \$4.]

THE increasing recognition of the influence of autogenetic products on the phenomena of disease has resulted in increased attention to the subject of physiological chemistry. In fact, we believe it will be but a few years before the teaching of ordinary chemistry will be relegated from the curriculum of medical colleges to that of preparatory schools, where it prop-

erly belongs, and as much of the medical student's time as has heretofore been devoted to general chemistry will be occupied by a laboratory course in physiological and pathological chemistry. The translator of this volume may have looked forward to the time when such a condition of affairs would ensue, but we believe that time is very near at hand.

This volume is admirably suited for laboratory purposes, as it describes the best methods for the preparation, detection, and quantitative estimation of most of the substances found in the organism. The author's work is condensed as much as is possible with a proper presentation of the principal results of physiologico-chemical research and with the methods of physiologico-chemical investigation. He has given considerable space to pathologico-chemical subjects.

We hope that in the next edition the translator will introduce such illustrations as will enhance the usefulness of the text.

The Essentials of Chemical Physiology, for the Use of Students.

By W. D. HALLIBURTON, M. D., F. R. S., Fellow of the Royal College of Physicians, and Professor of Physiology in King's College, London, etc. London and New York: Longmans, Green, & Co., 1893. Pp. xi-166. [Price, \$1.50.]

THE author of this volume is so well and favorably known to the profession by his text-book on chemical physiology and pathology that his name is a sufficient guarantee of the value of this work.

The increasing importance of its subject is everywhere appreciated in medical teaching, and this small volume is a guide to supply students with directions for examining practically the most important of the topics included under the heading of physiological chemistry.

The lessons are divided into those belonging to an elementary and those belonging to an advanced course. Each of the elementary lessons is supposed to occupy the student for an hour, while the advanced lessons will take about two hours to carry out. In an appendix there is a description of the special instruments used in medical chemistry.

The work is essentially a practical one, and, though meant entirely for students, it can not but be of value to the practitioner who may desire information regarding the methods of chemical examination as applied to medicine.

An Outline of the Embryology of the Eye. With Illustrations from Original Pen Drawings by the Author. By WARD A. HOLDEN, A. M., M. D., Assistant Surgeon, New York Ophthalmic and Aural Institute, and Clinical Assistant, Vanderbilt Clinic. New York and London: G. P. Putnam's Sons, 1893. Pp. 69. [Price, 75 cents.]

THIS essay, which took the Cartwright prize in 1893, is based on the examination of a great number of specimens, and is a valuable addition to the literature on the subject. It would be difficult to give even a synopsis without reproducing the entire essay, and the title clearly indicates its scope.

New Truths in Ophthalmology, as developed by G. C. SAVAGE, M. D., Professor of Ophthalmology in the Medical Departments of the University of Nashville and Vanderbilt University. Thirty-two Illustrations. Published by the Author, 1893.

EVIDENTLY, from the title of his book, Dr. Savage does not believe that there is nothing new under the sun. He has brought together a number of short papers, several of which have been read before medical societies, and in them he expresses his views on several subjects. While he has doubtless

demonstrated the accuracy of his views to his own satisfaction, it is doubtful if the whole world of ophthalmologists will accept all his "new truths," or if the author himself may not in the future modify them somewhat.

A Text-book of Ophthalmology. By WILLIAM F. NORRIS, A. M. M. D., Professor of Ophthalmology in the University of Pennsylvania, and CHARLES A. OLIVER, A. M., M. D., one of the Surgeons to the Wills Eye Hospital, Philadelphia. Illustrated with Five Colored Plates and Three Hundred and Fifty-seven Woodcuts. Philadelphia: Lea Brothers & Co., 1893. Pp. vii-19 to 641.

THE first part of this work, which was written by Dr. Oliver, is the better, and the chapters on embryology, macroscopic and microscopic anatomy, physiology, optics, and physiological optics are exceptionally good. These subjects occupy about a quarter of the entire work, instead of being dismissed with a few words, as is the case with too many otherwise good text-books, and are presented with reasonable fullness and detail. The chapter on the examination of the eye also is excellent. The remaining chapters of this part, though good, seem to show a little falling off from the fine work which precedes them. Possibly this may be because the same subject is treated of by Dr. Norris in the second part.

The second part, by Dr. Norris, is devoted to what may be called practical ophthalmology, the injuries and diseases of the eye and its appendages, their treatment, operations, and refraction. It seems a little strange to find the subject of refraction treated of in two places in the same book, as it is here—in one place by Dr. Oliver, in the other by Dr. Norris. If Dr. Oliver had increased the length of his chapters on the subject by the space occupied by Dr. Norris on the same subject, a very valuable article would doubtless have been the result. One would judge from what both write that neither had a working knowledge of the Javal-Schiötz ophthalmometer. It is difficult to write a criticism on the second part of the work, because it is not decidedly either better or worse than a considerable number of text-books on the same subject. It is a good, serviceable work as a whole.

Biblioteca Científica Moderna. Medicación y Medicamentos Cardio-motores. Por D. ANTONIO ESPINA y CAÑO, Médico por Oposición del Hospital Provincial de Madrid. Segunda Edición, corregida y considerablemente aumentada. Madrid: Administración de la Revista de Medicina y Cirugía Prácticas, 1893. Pp. vi-334.

THE volume is divided into three parts. Of these, the first is devoted to classification and general considerations on cardiac physiology and pathology; the second, to the study of drugs employed as cardiac stimulants and tonics; and the third, to morbid cardiac conditions and their therapeutics.

The book is well arranged and compact, yet sufficiently complete for its purpose, and contains much of value and interest. Its small and yet convenient size renders it particularly a comfortable book to read, and to this its flexible covers add yet more.

BOOKS, ETC., RECEIVED.

A Text-book of Physiology. By M. FOSTER, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge, etc. Fifth American from the Fifth English Edition, thoroughly revised, with Notes, Additions, and Three Hundred and Sixteen Illustrations. Philadelphia: Lea Brothers & Co., 1893. Pp. xvi-33 to 1083. [Price, \$4.50.]

Pyogenic Infective Diseases of the Brain and Spinal Cord.

Meningitis. Abscess of Brain. Infective Sinus Thrombosis. By William Macewen, M. D., Glasgow. New York: Macmillan & Co., 1893. Pp. xxiv-354. [Price, \$6.]

Atlas of Head Sections. Fifty-three Engraved Copperplates of Frozen Sections of the Head, and Fifty-three Key Plates with Descriptive Texts. By William Macewen, M. D. New York: Macmillan & Co., 1893. [Price, \$21.]

Surgery. A Manual for Students and Practitioners. By Bern B. Gallaudet, M. D., Demonstrator of Anatomy and Clinical Lecturer on Surgery, College of Physicians and Surgeons, New York, and Charles N. Dixon-Jones, B. S., M. D., Fellow of the New York Academy of Medicine and the British Gynecological Society, etc. Series edited by Bern B. Gallaudet, M. D. Philadelphia: Lea Brothers & Co., 1893. Pp. 6-17 to 301. [Price, \$1.75.] [*The Students' Quiz Series*.]

The Uniform System of Accounts, Audit, and Tenders for Hospitals and Institutions, with Certain Suggested Checks upon Expenditure, and Tender and other Forms for Securing Economy, and the Index of Classification. Compiled by a Committee of Hospital Secretaries, and adopted by a General Meeting of the same, January 18, 1893. By Henry C. Burdett, author of *Hospitals and Asylums of the World*, etc. London: The Scientific Press, Limited, 1893. Pp. 5 to 76. [Price, 6s.]

The Art of Massage. By A. Creighton Hale. Profusely illustrated with Original Drawings. London: The Scientific Press, Limited, 1893. Pp. xvi-144. [Price, 6s.]

Outlines of Insanity. An Attempt to Present in a Concise Form the Salient Features of Mental Disorder; Tabulated and arranged for Facility of Reference when Drawing up Lunacy Certificates. Designed for the use of Medical Practitioners, Justices of the Peace, and Asylum Managers. By Francis H. Walmsley, M. D., Leavesden Asylum, etc. London: The Scientific Press, Limited, 1892. Pp. vi-154. [Price, 3s. 6d.]

Mental Nursing, or Lectures for Asylum Attendants. By William Harding, M. B. (Ed.), M. R. C. P. (Lond.), Assistant Medical Officer, Female Department, Berrywood, Northampton, etc. London: The Scientific Press, Limited, 1893. Pp. vii-131. [Price, 2s. 6d.]

La pratique des maladies du système nerveux dans les hôpitaux de Paris. Aide-mémoire et formulaire de thérapeutique appliquée. Par le Professeur Paul Lefert. Paris: J. B. Baillière et fils. Pp. 8-9 to 285. [Prix, 3 fr.]

Hospice de la Salpêtrière. Clinique des maladies du système nerveux M. le Professeur Charcot. Leçons du professeur, mémoires, notes et observations parues pendant les années 1889-'90 et 1890-'91 et publiés sous la direction de Georges Guinon, chef de clinique. Avec la collaboration de MM. Bloch, Souques et J. B. Charcot, internes de clinique. Tome II. Paris, Felix Alcan, 1893. Pp. 482. [Prix, 12 fr.] [Publications du *Progrès médical*.]

Shipowners and Ships' Surgeons. Including Truth's Article, Doctors at Sea. By Charles Henry Lect, Fellow of the Royal College of Surgeons of England, etc. Seaforth: Liverpool, 1893.

Quinsy and its Treatment by Early Incision. By John Winters Brannon, M. D., New York. [Reprinted from the *Medical Record*.]

Insufficiency of the Ocular Muscles due to Errors of Refraction. By S. M. Payne, M. D., New York. [Reprinted from the *New York Polyclinic*.]

Epileptic Insanity. By James H. McBride, M. D., Wauwatosa, Wis. [Reprinted from the *Review of Insanity and Nervous Diseases*.]

Laughing Gas as an Anæsthetic in General Surgery. By T. L. Macdonald, M. D., Washington, D. C. [Reprinted from the *Southern Journal of Homæopathy*.]

Mechanical Aids in the Treatment of Chronic Forms of Disease. By George H. Taylor, M. D., New York. New York: George W. Rodgers, 1893.

Annual Report of the State Board of Charities. For the Year 1892.

The Measured Effects of Certain Therapeutic Agents, among which especially are Lavage, HCl, and Intra-gastric Electricity, upon the Secretory and Motor Functions of the Stomach in Cases of Chronic Catarrh (Glandular Gastritis). [Reprinted from the *Therapeutic Gazette*.]

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

The Search for a Method of extracting Cataract which will enable us to avoid Incarceration and Prolapse of the Iris.—Nicoti (*Archives d'ophtal.*, December, 1892) offers the following aphorisms: 1. Ordinary iridectomy prevents prolapse, but does not prevent incarceration. 2. A fenestrated iridectomy renders incarceration and prolapse less frequent, but does not prevent them altogether. 3. Only a very large iridectomy seems to be absolutely efficacious. 4. Flap cystiotomy made simultaneously with the corneal section prevents capsular incarceration better than other methods. 5. A conjunctival flap protects the scar from the grave dangers of incarceration and prolapse.

The Ætiology of the So-called Retinitis Proliferans.—Schultze (*Arch. of Ophthalm.*, xxii, 2) thinks that vitreous or retinal hemorrhages are always present, and to these may be attributed the chief rôle in the development of the affection. He believes that the new masses seen in the fundus are not inflammatory or exudative, but rather deposits of unabsorbed blood-fibrin. The deposits are in intimate connection with the retina and cause atrophy of the nervous elements of the retina and hypertrophy of the connective-tissue elements, and finally become themselves transformed into finely fibrous cicatricial tissue. Since in every case vitreous hemorrhages are found at some period, it is probable that we have to do here with an imperfect absorption of blood coagula which become adherent to the retina, and finally lead to a proliferation of the connective-tissue framework of the retina. Schultze considers the name "retinitis proliferans" unsuitable for this affection, since an inflammation of the retina has never been observed as the primary disease, while retinal and vitreous hemorrhages are always found. The remains of these hemorrhages finally form the white deposits on the retina, which are nothing more than unabsorbed masses of fibrin precipitated on the retina, that in the course of time assume the appearance of connective tissue, and cause fibrous degeneration of the underlying retina.

The Treatment of Ptosis.—Meyer (*Arch. of Ophthalm.*, xxii, 2) has devised an apparatus for the treatment of traumatic ptosis, which consisted originally of the finest steel wire, but which he subsequently changed to wire of eighteen-carat gold. This he folded upon itself and bent into a loop, the upper convex branch of which was pushed, with a fold of skin of the upper lid, up under the superior orbital margin. The lower branch was so formed as to lie close beneath the eyelashes of the lower lid, and so bent under the internal canthus that it found support against the nose. In order to obtain sufficient elasticity, a sort of loop corresponding to the external canthus was made, and the two free ends were made to terminate in

small buttons. In order to prevent the winking of the lids from thrusting out the wire, an angular bend was given to the upper branch which succeeded perfectly. The thickness of the wire, as well as the length of the interposed spring, and the elasticity and mechanical resistance of the lid elevator, must be fixed by experiments.

Pulsating Exophthalmia following a Fracture at the Base of the Skull.—Despagnet (*Rec. d'ophthal.*, May, 1893) reports an interesting case of this nature occurring in a woman, aged sixty, who was run over by a carriage, and was picked up unconscious and bleeding from the left nostril and left ear. The bleeding soon stopped, but recurred profusely during the night. The patient complained constantly of severe headache at the vertex and of a buzzing noise like a saw on the left side of the head. Six days later the eyelids became edematous on the right side, the right eye protruded, and the conjunctiva was chemotic. There was no pulsation then, but at the end of the third week it appeared at the supero-internal angle, and the presence of an arterio-venous aneurysm was no longer doubtful. Constant orbital compression over the closed eye by means of an elastic bandage was continued from the first, and by the end of the sixth week there was a perceptible diminution of the exophthalmia. The eye was totally blind and eventually the cornea partially necrosed, but at the end of the ninth month the exophthalmia had disappeared, though the pulsation remained. Motility of the eye was nearly abolished. The left eye remained intact throughout.

The Interrupted Blood Column in the Vessels of the Eye.—Friedenwald (*Ophth. Rev.*, June, 1893) considers that in cases of sudden blindness due to an interrupted blood current in the retinal vessels, the circulating blood in the vessels breaks up into colorless and colored parts, into parts free from red corpuscles, and parts in which the latter become aggregated in masses, and that this occurs when the current is greatly retarded. This would explain the fact that the phenomenon has been seen much oftener in veins than in arteries. The fact seems to force the conclusion that there is cohesive attraction between the red blood-corpuscles, which naturally manifests itself only when the current is very slow.

The Extraction of a Bullet from the Orbit which had remained there for Twenty-three Years.—Rosse (*Rec. d'ophthal.*, June, 1893) reports the case of a man, aged fifty years, who had been shot in the right eye at the battle of Sedan in 1870. The conjunctiva was red and swollen, and at the bottom of the orbit appeared a small black mass about four millimetres in diameter, which, after repeated attempts, was removed, and proved to be a lead bullet two centimetres long and weighing thirty-two grammes. The left eye had remained intact throughout, with perfect vision. The orbital walls were totally uninjured.

Congenital Serous Cysts of the Orbit; Anophthalmia and Microphthalmia.—Fromaget (*Arch. d'ophthal.*, June, 1893) reports a case of this nature, and concludes from his investigations that a large part of the tumor contained a cavity lined with glandular, cylindrical epithelium, into which cavity opened numerous diverticula lined with similar epithelium. The cyst was really bilobate, the elongated portion corresponding to the optic nerve, while the larger, rounded portion pushed the lid forward. The chemical examination of the contents of the cyst enabled him to eliminate any cerebral origin to the tumor, while the microscopic examination proved it to have been derived from a mucous membrane. He concludes that in the embryo a portion of the naso-lacrimal mucous membrane was encapsulated in the orbit and gave rise to the cyst.

The Vision in Circles of Dispersion.—Salzmann (*Arch. für Ophthal.*, xxxix, 2) concludes from his investigations that the

diminution of the acuity of vision experienced in circles of dispersion is entirely independent of the dioptric construction of the eye. The variations in the acuity of vision depend entirely upon the width of the pupil, the defects of accommodation, and the coefficient of practice. The latter can only be determined empirically, and this renders it impossible to determine with any exactness the visual acuity.

The Pigment of the Eye.—Scherl (*Arch. für Ophthal.*, xxxix, 2) writes in a way that makes it almost impossible to make an intelligible abstract. He finds that the absence of any vascular system in the interior of the eye in birds explains the constant appearance of pigment early in life on the external surface of the proximal lamella. In all mammalia and in man, where an internal vascular system is met with, the pigment is formed first upon the inner surface of the proximal lamella. There is here a direct dependent relationship between the nearness of the vascular system and the development of the pigment.

The Development and Extension of Orbital Sarcoma.—Holden (*Arch. of Ophthal.*, xxii, 3) gives the results of his examination of three cases of sarcoma of the orbit. The three cases exhibit the different starting points which those growths may have—one springing from the periosteum, and being for the most part fibrous; another having its origin in the cellular tissue of the orbit, and being composed almost entirely of small cells; and the third arising in the choroid and extending back through the optic nerve, forming cellular foci in the dura sheath of the nerve and elsewhere in the orbit. In all these cases the cells of the younger, developing portions of the tumor, the sarcoma cells in the infiltrated tissues, and the sarcomatous foci at a distance from the main growth, could for the most part be traced to the proliferation of the adventitial or endothelial cells of vessels, which were continuous with those of the mass of the tumor. The fibrous tissue in the substance of a sarcoma, or forming its capsule or sheath, may have three sources of origin: 1. It may be simply the previously existing tissue of the part changed in its relations by the development of the sarcoma cells. 2. It may be new tissue formed in the usual way by the proliferation of connective-tissue cells or formative cells. 3. It may be developed by the proliferation of the adventitial cells of vessels. Holden is of the opinion that sarcoma of the orbit develops mostly from the proliferation of the adventitial cells and more rarely of the endothelial cells of vessels. Even dense connective-tissue membranes and capsules offer little resistance to the extension of sarcoma when the vessels of the tumor are continuous with those of the membrane.

Bilateral Hemianopsia.—Schmidt-Rimpler (*Archives of Ophth.*, xxii, 3) reports an interesting case occurring in a man, aged fifty-one years, who was struck on the head by a heavy stone, and who died four years and a half later. The autopsy revealed diffuse hematoma and cicatricial contraction in the region of the injury, foci of softening in the border between the gray and white substances, in the right temporal lobe an apoplectic cyst, and in the right cerebellar hemisphere apoplectic cysts. The hemianopsia homonyma dextra was preceded by headache and paresis of the right extremities with clonic spasms. A year later, after a short prelude of subjectively observed contraction of the field, absolute total blindness suddenly ensued. A small central visual field was gradually restored, but slowly became reduced to a minimum. The autopsy revealed as the cause of the first right-sided hemianopsia a hematoma of the dura mater. The right paresis must be regarded as a sequence of the extensive cicatricial contraction in the posterior central convolution. The yellowish foci of cheesy matter in the region between the gray and white substances in

the posterior portion of the right posterior lobe may explain the later loss of the left visual field.

The Position of the Source of Light and the Observer in Skiascopy.—Jackson (*Arch. of Ophth.*, xii, 3) holds that with a plane mirror the lamp flame should be brought as close to the mirror as possible. With a concave mirror the immediate source of light is brought to its most desirable position by carrying the original source as far behind the patient as possible. The closest approach to accuracy will here be made in the determination of the nearest point to the patient's eye that the light in the pupil moves with the light on the face. In order to bring out most distinctly the characteristic band-like appearance of the light in the pupil, the observer must place his eye at the point of reversal for the meridian in which he wishes to obtain the band and place the immediate source of light at the point of reversal for the other principal meridian.

Movements of the Upper Eyelid associated with Lateral Movements of the Eyeball.—Friedenwald (*Arch. of Ophth.*, xii, 3) reports several cases of this peculiarity, and finds that the peculiar associated movements under consideration may occur in a variety of conditions, without any paralysis or with paralysis of the external or internal rectus, and that it may be both congenital and acquired. He finds that there may be contraction of the orbicularis associated with movements of the jaw or the contraction of various facial muscles. Or there may be contraction of the levator palpebræ superioris associated with the act of moving the jaw or of swallowing, or finally there may be contraction of the levator associated either with abduction or with adduction of the eyeball.

Orbital Lower-lid Cysts with Microphthalmia or Anophthalmia.—Mitvalsky (*Arch. of Ophthal.*, xii, 3) draws the following conclusions from his observations: The spoon-shaped ball open below may be considered as developed from the proximal layer of the primary optic vesicle. This layer produces first in the usual way the single stratum of pigment epithelium. The bordering mesoblast then begins to form a chorioid and fairly typical sclera. Anteriorly the cornea and iris are developed later. All the products of the distal layer of the primary vesicle are found hanging to the rudiment of the ball, surrounded by a fibrous wall, which also incloses a large orbital lower-lid cyst. The distal layer of the primary optic vesicle retains, however, its original position, while the absence of the lens shows that no invagination of the secondary optic vesicle occurred. The secretion of the ocular fluid in these cases goes hand in hand with the development of the coats of the eye. The current from the retinal epithelium takes the direction of least resistance and passes into the folded products of the distal layer developing in the neighboring mesoblast and distending them. When a fibrous sheath has formed about these products, the weaker portions of this sheath yield, and a large reservoir is formed, preventing the proper development of the inferior orbital wall and eventually pushing out the lower lid.

A New Phorometer.—Prince (*Arch. of Ophth.*, xii, 3) has devised a phorometer which consists of two prisms of two degrees each, combined with a Maddox rod. He claims for it the following advantages over the simple Maddox rod:

1. It removes the possibility of preconceptions on the part of the patient.
2. It avoids the necessity of an explanation of terms to the patient.
3. It avoids the errors from fatigue due to delays occasioned by the changing of prisms.
4. It indicates the character of the heterophoria.
5. It indicates the manifest quantity to a fraction of a degree.

6. It saves the time of the observer.

7. Its simplicity and inexpensiveness, together with the rapidity and accuracy with which the presence or absence of heterophoria is determined, render it of special diagnostic value to the general practitioner or neurologist.

Two Cases of Ophthalmoplegia Externa with Paresis of the Orbicularis Palpebrarum.—Hughlings Jackson (*Lancet*, July 15, 1893) reports two cases which, in their clinical aspects, support Mendel's theory that the fibers supplying the orbicularis palpebrarum arise from the nucleus of the third nerve, although they come out by the facial.

Observations on Ring Infiltration of the Cornea.—Collins (*Ophth. Rev.*, August, 1893) considers that ring infiltration of the cornea, so far as four cases indicate, seems to be an affection which follows perforating septic wounds of either its central or peripheral portions. Whatever the locality of the wound, the ring of infiltration occupies precisely the same position, its outer edge being one millimetre distant from the corneal margin. The ring forms very rapidly after the infliction of the wound. It is accompanied by pus in the anterior chamber. Microscopically, the cell accumulation between the lamellæ of the cornea is seen to be densest at a position almost equidistant from its anterior and posterior surfaces. The area of cornea within the ring is at first quite free from infiltration, but later a general diffuse cellular increase is observed throughout the entire cornea.

The Rod Test with the Rotary Variable Prism.—Jackson (*Ophth. Rev.*, August, 1893) advises that, for the fixed prism, the rod should be ground with its flat side inclined to the cylindrical surface, so that it exerts a prismatic action in the direction of its length. The angle chosen for the rotary prism is five centrats, with an equal prismatic effect given to the rod. In the primary position they exactly neutralize each other; and by rotation of the prism through 180° every effect up to the maximum of ten centrats is produced. The rotary prism must be turned almost 37° before one centrat of change in prismatic effect is produced. With it the lowest degree of deviation can be measured with minute accuracy.

Lamellar Cataract in Elderly Persons.—Hirschberg (*Contrib. f. prakt. Aug.*, August, 1893) considers that lamellar cataract is due to some transient affection of the foetal lens, and is the most frequent form of lens opacity met with in children and young persons. It is excessively rare in elderly persons, and De Wecker believes that its rarity here is due to its transformation into total cataract. Hirschberg, however, believes that there are three possible reasons for its rarity: 1. Patients with lamellar cataract die early. 2. The lamellar cataract changes to total cataract in course of time. 3. The lamellar cataract remains unchanged, but is very difficult to recognize in elderly persons. The first proposition may be discarded as untrue. The second condition may be regarded as occurring very rarely. Lamellar cataracts have been repeatedly under constant observation for years without any change being noticed. Still, occasionally such change has been noticed, the opacity becoming denser while its diameter may remain unchanged. This change is difficult to recognize unless the iris has been dilated.

The Treatment of Ulcers and Abscesses of the Cornea by Scraping and Irrigation.—De Wecker (*Ann. d'oc.*, July, 1893) claims that this treatment of corneal abscesses and ulcers by thorough scraping and subsequent irrigation gives surprising results, as follows: 1. The almost instantaneous suppression of pain and photophobia. 2. The clearing up of the surrounding parts, followed by much more rapid healing than by any other means. 3. Repair by a more transparent tissue than that which follows other methods of treatment.

Ocular Syphilis and its Treatment.—Chibret (*Ann. d'oc.*, July, 1893) concludes his paper on this subject by three propositions: 1. The best mode of general treatment for all forms of ocular syphilis consists in hypodermic injections of soluble salts, and especially of HgCy. 2. The disadvantages of injections of soluble salts are the local pain, which is, however, bearable, and the diarrhœa, which, as a sign of acute mercurial poisoning, may be easily avoided. 3. Potassium iodide has no specific value against syphilis, but it facilitates the elimination of the mercury and combats chronic poisoning. Its addition to a mercurial treatment diminishes the specific effect of the latter.

A New Scotometer.—Antonelli (*Ann. d'oc.*, July, 1893) has devised a scotometer which has some advantages. In place of the ophthalmoscopic mirror there is a metallic disc having a circular hole at its center, which by means of a button can be made to vary in diameter from one to fifteen millimetres. A needle at one side indicates in millimetres the diameter of this hole. Each of the two discs corresponding to the two lens-bearing discs of the ophthalmoscope is perforated at its periphery by eight holes of a diameter of fifteen millimetres. The anterior of these two discs has one empty hole and the other seven holes are covered by discs of colored paper—white, deep yellow, red, orange, green, blue, and violet. The posterior disc carries eight glasses, one dense white, and the others are pale red, deep red, bright green, deep green, blue, violet, and yellow. In examining the color sense of the patient by daylight we use the first disc; if by artificial light, we use the second disc. A detailed description of the method of using the instrument follows.

Instantaneous Photography of the Fundus of the Human Eye.—Guilloz's (*Arch. d'Ophthal.*, August, 1893) method consists in photographing the inverted image of the fundus. His apparatus consists of a magnifying glass, a lamp, and a photographic camera. The magnifying glass is a lens of D. 15 to D. 20 taken from a case of trial lenses. It is fixed by its mounting between the teeth of a support which permits of its being moved in all directions. The lamp is an ordinary movable gas lamp, in which the ordinary chimney is replaced by a chimney of sheet-iron, pierced by two openings, the axes of which are perpendicular. Both are supplied with a cylindrical margin. The largest, three centimetres in diameter, holds a tube containing at its end a lens of D. 18. The focus of this lens occupies the position of the flame. It is protected by a disc of plane glass of the same diameter from the products of combustion of the magnesium mixture projected automatically into the flame when desired. Into the other flange works a little instrument called a magnesium pistol. A square rod glides in a similar opening at the base of a cylinder of which the other free, open extremity is capable of being adapted to the lamp. This rod terminates in the cylinder by a spoon, and its other end is threaded so as to fit into a screw-nut which limits the excursions of the rod in the cylinder. A roller spring placed in the pistol concentrically with the rod bears by its two ends against the posterior wall of the instrument and against the vertical posterior border of the spoon. The pistol is loaded by drawing on the posterior end of the rod; the spring is compressed, and a movable lever by its own weight catches the hook at one of its extremities in a little notch in the lower part of the rod. There is an opening in the upper wall of the cylinder on the same level with the spoon. Through this may be introduced into the spoon from gr. 0.20 to gr. 0.30 of a mixture of magnesium and potassium chlorate. At the moment of taking the plate a rubber bulb fitted to the photographic apparatus is compressed; this action raises a little piston, which, acting on the other end of the lever, aids in throwing the magnesium mixture into the flame. The combustion is so

prompt that the instantaneous diaphragm is done away with and is replaced by the instantaneous action of the light. After each combustion the tube containing the lens should be withdrawn in order that the plane glass which protects it may be cleansed. A long description of the camera employed and of the method of operating follows.

Metastatic Inflammations in the Eye, and Retinitis Septica.—Herrnbeiser (*Zeitsch. für Heilk.*, xiv, 1893) has observed retinitis septica in about thirty per cent. of the cases examined, covering a period of about seventeen months. He gives the results of the microscopical examination of six cases, in all of which death resulted. In his opinion, the invasion of the micro-organisms and the products resulting from their action cause a chemical change in the blood, which is answerable for the extravasation of blood in the retina. It leads to a general poisoning of the system caused by the absorption of the poisonous material produced by the bacteria, and induces manifold changes in all the different organs of the body. The extravasation of blood in sepsis is the expression of a previously existing disturbance of nutrition in the walls of the blood-vessels, and is not caused by embolic obstruction of the vessels.

The Weiss Reflex as a Sign of Myopia.—Randall (*Ophth. Rev.*, September, 1893) thinks that this curved reflex, parallel and close to the margin of the disc, may be recognized much more frequently if carefully looked for with a strong concave mirror, such a mirror being calculated to emphasize all the retinal reflexes. No positive statement can be made as to its significance, but it is conspicuous in some cases of distending eyeball. It may also be seen in eyes showing no tendency to distention, while on the other hand some cases of progressive myopia do not show it.

Convergent Squint and its Treatment.—Thompson (*Ophth. Rev.*, September, 1893) thinks the operation for convergent squint, when considered by the light of the ultimate result, one of the most difficult, uncertain, and unsatisfactory in ophthalmic surgery. Many patients never acquire binocular vision, because of some inability to join the two cerebral pictures of the same object. He believes that the principal cause of the difficulty of its correction is the fact that all of the muscles which turn the eye play an important part in its causation, and that both they and the connected fascia come to have altered relations with the eyeball, which are not readjusted by a simple tenotomy. In children, glasses give relief sometimes, but rarely. When simple tenotomy is done, the effect of the operation should be divided between the two eyes. He prefers the combination of tenotomy with advancement, but the advancement should always be capsular. He advocates advancement upon one or both eyes, with or without tenotomy, in all cases after the thirteenth year.

The Repair of Staphylomatous Cornea.—Scott (*Ophth. Rev.*, September, 1893) considers it possible in many cases of markedly staphylomatous cornea, where the other structures of the eye are practically intact, to excise a portion of the staphyloma, and then, by the use of sutures, to convert into a simple leucoma, which may be eventually tattooed, what was previously an unsightly, irritable, and irritating deformity; and in some cases to restore a certain amount of useful vision by means of an artificial pupil. He uses a knife, in preference to scissors, in removing the corneal tissue, because the cut is cleaner and no squeezing action is exerted on the tissues. Care should be taken to avoid the direct apposition of the free corners of flaps of tissue. The operation is done in the same way as in former operations for the removal of staphylomatous tissue, and the stitches are tied very lightly, so as to avoid any undue tension. The dressings are changed twice daily.

A Blepharostat.—Terson (*Arch. d'Ophthalm.*, September, 1893) has devised a blepharostat which he maintains answers to the three following indications: 1. The septic rubbing of the ciliary margin and cilia is prevented by the spoons of the instrument, which resemble those of Panas's instrument. 2. The instrument can be instantaneously removed, the limitation of the stretching or opening be made by a screw, which runs, as in Desmarre's lid forceps, outside the arms on a spiral rod. The spring is sustaining for all violent movements of the lids. If the patient is very intractable, the arms may be solidly fixed wide open by a washer of metal running within the arms on the preceding rod. 3. The articulation at the level of the spoon arms, which has also been employed by both Abadie and Vacher, allows the instrument to be employed at the internal or external angle.

Edison's Electric Pen in Ophthalmology.—Maklakoff (*Arch. d'Ophthalm.*, September, 1893) concludes as follows from his investigations into what he calls "tetanization" of the eye: 1. In normal eyes with normal tension, tetanization of short duration, either directly on the eyeball, or indirectly through the lids or through rubber bladders filled with water, causes a marked lowering of the tension. 2. In eyes with increased tension, especially in glaucomatous eyes, immediate lessening of tension may be induced. 3. In other cases of hypertonus the tension sometimes increases, but this does not last long. 4. The tetanization produces a surprising effect in traumatic cataract by promoting absorption of the cortex. 5. In some cases of sympathetic iridocyclitis, tetanization causes extraordinary amelioration. 6. In some cases of complete posterior synechia the hypertonus is considerably reduced and remains so for some time.

The Influence of Recession of the Eyeball upon the Refrangibility of the Correcting Cylinder in Different Forms of Astigmatism.—Ostwalt (*Arch. d'Ophthalm.*, September, 1893) draws the following practical conclusions: If the optometric examination does not place the axis of the correcting cylinder in the same axis as that existing in the prescribed glasses made by the optician, the correction gained by these lenses will be inferior to that obtained by the ophthalmometer. The difference will be the greater as the axis of the cylinder obtained by the ophthalmometer is further removed from that in the lenses prescribed in the usual way, and as the spherical ametropia accompanying the astigmatism is the greater. Other things being equal, the difference will be greater in compound myopic than in compound hypermetropic astigmatism.

Miscellany.

The Medical Society of the County of New York.—In his presidential address before the society, delivered on the 27th of November, Dr. Seneca D. Powell said that he was satisfied that injustice and embarrassment were occasioned by the readiness of the community to abuse opportunities for free treatment, together with the indifference of many physicians and their failure to investigate and to discriminate in such cases. It was not his thought to check a real benevolence. He would be the last man to deny the benefits of science to the poor. It was the glory of the city that no one, in whatever extremity of poverty, needed to perish or suffer for lack of prompt and skillful medical attention. But the policy, or at least the practice, of many dispensaries and hospital associations put a premium on meanness and withdrew from the local practitioner his natural clientage by compliantly serving at the free dispensary

those who were abundantly able to pay for what they received. Our leading physicians and surgeons connected with these charitable institutions were more or less responsible for this state of things. He freely admitted that the case presented some difficulties, but surely new rules or more conscience, care, and discrimination were demanded. A most public and flagrant instance was furnished by the course of the board of health in its recent crusades of wholesale vaccination. There was, perhaps, little to be said of the work in Cherry Street and the like; but when it came to the free vaccination of the employees of prosperous business houses and rich corporations, and even business men themselves, the preposterous extent of the abuse and the consequent professional injury were seen at a glance. Such things could not occur did not physicians lend themselves to the scheme. He would prefer to believe it was done thoughtlessly, and he trusted that a declaration on the subject by the society would do much toward correcting such abuses.

Again, whenever a man put a low estimate on the importance and value of his own services, he so far lowered the medical standard, and thereby injured his professional brethren. Why reputable physicians should consent to serve rich corporations for nominal returns would seem hard to explain. But the anomaly existed. Many instances illustrative of those misplaced favors would occur to the minds of those present. In this regard the legal profession set a different example and one worthy of emulation. So far from belittling the importance of his own service, to the injury of his profession, the corporation lawyer exacted the highest fees and those commensurate with the interests involved. Why should the physician adopt an opposite course?

Another point to which he called attention was the matter of expert medical testimony in the courts. Comparatively recent events in connection with some trials of peculiar public interest had given this subject special prominence. His impression was that the result had been to discredit the value of expert testimony in general. It was evident that in the case of conflict or apparent discrepancies between the testimonies of reputed experts, neither the public, the ordinary jury, the bar, nor indeed the bench, had the special training to discriminate between true and false and to estimate duly the scientific value and the proper influence of the facts in a given case. The result was to create an impression of vagueness and a natural distrust of medical science. Such a matter, at first thought, might seem beyond the power, if not the province, of the society, but he would suggest that it was not really so. Both in the interest of civil justice and in that of the profession the evil might be rectified by the appointment from the society of a commission or jury of competent physicians to review and to pronounce upon the entire expert testimony in each given case. The summing up by such a commission would in the highest degree inspire confidence and serve the ends of justice. Of course such a procedure must be authorized by statute law.

There was another very important consideration affecting the society's relation to the profession at large, the State, and the community. It was an undeniable principle that with a responsibility of any sort must go the power and the supervision in the matter under consideration. Now, since this was the legally instituted and recognized Medical Society of the County of New York, and the body in which inhered the major responsibility for whatever action might be taken affecting medical affairs, it followed that all legislation relating to the practice of medicine, either as between physicians or between the physician and the community, should be first submitted to the society and receive its approval before it was transmitted to the State society or proposed for enactment and

law. In view of all that had been said upon this subject and of the necessities of the case, the propriety of adding to the standing committees one on Legislation, to the special care of which might be committed all such matters, often among the most important upon which the society might be called to take action, must be manifest.

Efforts to Limit the Spread of Tuberculosis and Diphtheria.—The following report by Dr. Cyrus Edson, chairman of the Sanitary Committee of the Board of Health of the City of New York, was adopted by the board on the 13th inst.:

The report of Dr. Hermann M. Biggs, the bacteriologist of this department, relative to tuberculosis is, in the opinion of the chairman of the sanitary committee, timely and well advised. The subject is well summed up in the three facts relative to the disease set forth, to wit:

First, tuberculosis is a contagious disease and is distinctly preventable. Second, it is acquired by direct transmission of the tubercle bacilli from the sick to the well, usually by means of the dried and pulverized sputum floating as dust in the air. Third, it can be largely prevented by simple and easily applied measures of cleanliness and disinfection.

The following recommendations based upon the foregoing premises are approved and offered to the board for its consideration:

First, that a circular be prepared for distribution among the people, setting forth the danger of contagion from tuberculosis and the fact that the discharges from the lungs of tubercular patients are dangerous not only to others but also to the patient afflicted, and also setting forth the danger of expectorating in places where the sputum is liable to be dried and carried by the air in the form of dust.

Second, that physicians and other persons to whom the knowledge of the existence of a case of tuberculosis may come be requested to report to this department all such cases within seven days of the time when such sick person comes under observation.

Third, the medical sanitary inspectors should, as a part of their duty, investigate cases of the disease reported and take specimens of the sputa for diagnostic purposes, as is done in cases of diphtheria. These specimens should be transmitted to the division of bacteriology for examination, and the division of bacteriology should be properly equipped for such examination, for the purpose of obtaining definite knowledge upon which the proper sanitary surveillance of those suffering from tuberculosis can be based. Upon the verification of the diagnosis, the inspector should visit the physician reporting each case and request him to fully instruct his patient and the persons with whom he is in contact concerning the nature of the disease and the danger of its transmission. If the case is reported by laymen, or if the physician prefers that the inspector should assume the aforesaid duty, then the inspector should personally perform this service.

Fourth, the following preamble and resolution should be adopted and sent to each of the general hospitals and to the Commissioners of Charities and Correction:

Whereas, Tuberculosis is a contagious disease and is distinctly preventable; and

Whereas, It is acquired by the direct transmission of the tubercle bacilli from the sick to the well, usually by means of the dried and pulverized sputum floating as dust in the air; and

Whereas, It can be largely prevented by simple and easily applied measures of cleanliness and disinfection, and to some extent by segregation of those suffering from it; be it therefore

Resolved, That this board urge upon hospital authorities of

the city of New York the importance of separation so far as possible in the hospitals of this city of persons suffering from pulmonary tuberculosis from those affected with other diseases, and urge that proper wards be set apart for the exclusive treatment of this disease; and be it further

Resolved, That the Commissioners of Charities and Correction be recommended to take such steps as will enable them to have and control a hospital to be known as the Consumptive Hospital, to be used for the exclusive treatment of this disease, and that, as far as practicable, all inmates of the institutions under their care suffering from tuberculosis be transferred to this hospital.

Fifth, it is recommended that the disinfecting corps disinfect places where evidence of infection from tuberculosis exists, whenever in the opinion of the chief inspector of contagious diseases it shall be necessary.

Sixth, it is recommended that suitable receptacles for sputa (cuspitors) be provided and properly cared for in all places where persons are brought together or caused to congregate for any purpose, especially in factory buildings.

The board has issued the following circular to physicians, prepared by Dr. Hermann M. Biggs:

During the last few months a series of investigations has been made in the bacteriological laboratory of the Health Department to determine how long the Loeffler bacilli remain in the throat after the disappearance of all false membrane in cases of diphtheria. The results obtained are extremely significant, and have caused the department to establish a new rule regarding the discharge from observation of patients who have suffered from diphtheria and regarding the time of disinfection of the premises.

During the past three months four hundred and five cases of true diphtheria have been subjected to repeated bacteriological examinations performed at short intervals during the course of the disease and during convalescence. In all of these cases cultures were made at the beginning of the disease, again after the lapse of three or four days, and finally at short periods after the complete disappearance of the false membrane, until the throat was found to be free from the diphtheria bacillus. In 245 of these 405 cases the diphtheria bacilli disappeared within three days after the complete separation of the false membrane; in 160 cases the diphtheria bacilli persisted for a longer time—namely, in 103 cases for seven days, in 34 cases for twelve days, in 16 cases for fifteen days, in 4 cases for three weeks, and in 3 cases for five weeks after the time when the exudation had completely disappeared from the upper air-passages. In many of these cases the patients were apparently well many days before the infectious agent had disappeared from the throat. These results show that in a considerable proportion of cases persons who have had diphtheria continue to carry the germs of the disease in their throats for many days after all signs of the disease have disappeared. No doubt the disease is largely disseminated by these persons, who are apparently well and who mingle with others while their throat secretions still contain the diphtheria bacilli.

These experiments have led the Health Department to adopt the rule that no person who has suffered from diphtheria shall be considered free from contagion until it has been shown by bacteriological examination, made after the disappearance of the membrane from the throat, that the throat secretions no longer contain the diphtheria bacilli, and that until such examinations have shown such absence the person must remain isolated and under observation. Disinfection of the premises, therefore, will not be performed by the department until examination has shown the absence of the organisms.

Secondary cultures, as in the case of primary cultures, may

be made by the attending physician, if he so desires; otherwise they will be made by the inspector of the district in which the case occurs. This applies only to cases occurring in boarding houses, hotels, and tenement houses, not to those occurring in private houses.

In this connection an interesting observation has been made showing that in diphtheria cases which have been subjected to frequent irrigation with antiseptic solutions from the beginning of the disease the bacilli, as a rule, disappear far more rapidly than in those in which such irrigations have not been employed. The department would feel grateful for any data which physicians of the city may furnish as to the treatment employed in each case, in order that more reliable conclusions may be reached as to the best mode of treatment.

The New York Academy of Medicine.—The programme for the meeting of Thursday evening, the 21st inst., included a paper by Dr. H. G. Piffard, on The Babcock Test as a Means of Determining the Commercial and Nutritive Value of Milk (Bovine and Human); and one by Dr. Thomas M. Pooley, on Asthenopia not Dependent upon Errors of Refraction or Insufficiency of the Ocular Muscles.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 27th inst., Dr. Emil Mayer is to read a paper on The Treatment of Follicular Pharyngitis; and Dr. W. H. Park, one on The Bacteria present in the Human Throat and their Relation to Acute Throat Inflammations.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 28th inst., Dr. George M. Edebohl will read a paper on The Radical Cure of Umbilical Hernia; and Dr. Henry C. Coe, one on Hysterical Manifestations due to Alcohol.

Guaiaicol.—At a recent meeting of the Paris Society of Biology, a report of which we find in the *Union médicale* for November 30th, M. Gilbert and M. L. Maurat presented a communication in which it was remarked that guaiaicol was one of the derivatives of creasote that had been most experimented with. The liquid guaiaicol found in commerce, the authors went on to say, meaning the guaiaicol obtained from creasote, was far from being almost a chemically pure product. It was a mixture of cresylol, guaiaicol, and creasote in varying proportions; it might contain fifty per cent. of guaiaicol, but sometimes it contained no more than twenty or even ten per cent. Pure guaiaicol occurred in the form of hard, white rhomboidal crystals, almost insoluble in water, but soluble in alcohol, in oil, and in anhydrous glycerin. The taste of guaiaicol is slightly sugary, with a pungent and burning after-taste. Pure guaiaicol has been prepared synthetically by Behel and Chouy, and it was this product that the authors had used in their experiments. The amount of guaiaicol, dissolved in glycerin or olive oil, necessary to kill a guinea-pig weighing a kilogramme is between five and fifteen grains, given hypodermically; it takes twenty-three grains given by the mouth to produce the same result. With a liquid guaiaicol obtained from Germany, containing forty-six per cent. of guaiaicol, 3.6 per cent. of cresylol, and 50.5 per cent. of cresol and homocresol, from fifteen to twenty grains were found necessary to kill a guinea-pig weighing a kilogramme. This product, therefore, is less poisonous than pure guaiaicol, but it contains less than half of the active principle. The chief effects of poisoning with guaiaicol are agitation and then enfeeblement with retardation of the heart's action and of the breathing. Most of the secretions are increased in quantity, especially the lacrymal secretion. At the moment of death, which occurs during coma, the thermometer may fall as low as 68° F. [*jusqu'à 20°*]. The biological effects of liquid guaiaicol resemble those of solid

guaiaicol, but the reduction of temperature and the increase of the secretions are less pronounced. The authors have used synthetic guaiaicol for several months in a certain number of cases of consumption in various stages. They have given it in daily quantities of from six to eighteen grains, in the form of pearls, each containing three grains of the active principle in oily solution. As a general thing, the stomach bears the drug well if it is taken immediately before eating. Sometimes large doses cause vomiting, but this may be avoided easily by testing the patient's susceptibility by administering progressively increasing doses of the synthetic preparation.

The Use of Thiol in Dermatology.—The *Nouveaux remèdes* for November 24th contains an abstract of an article by Dr. Laughin, published in the *Allgemeine medicinische Centralzeitung* and summarized in the *Centralblatt für die gesammten Therapie*, on the use of thiol in skin diseases. The journal first mentioned introduces the subject by stating that thiol is a dark-brown substance of agreeable odor and neutral reaction, readily soluble in water, less soluble in alcohol and in ether, and found in the market either dry or in thirty-per-cent. watery solution. Dr. Laughin has used thiol in the treatment of eczema of the nostrils, follicular eczema of the nasal orifices, and eczema of the upper lip. After having softened and removed the crusts, opened the pustules, and cleansed the entire region antiseptically, he applies an ointment consisting of four parts of thiol and thirty parts of lanolin. Thiol is used as a diapsma in cases of intertrigo; in papular eczema the solution is used. In acne vulgaris the affected portion of skin is covered twice a day for from ten to fifteen minutes with an ointment of five parts of thiol and thirty parts of lard. Thiol has been shown to be very useful also in acne rosacea, zoster, carbuncle, and boils. It is given internally in doses of from half a grain to fifteen grains three times a day. The advantages of thiol over ichthylol are that it does not give rise to any disagreeable after-taste, is odorless, and does not disturb the digestion.

The late Dr. William F. Hutchinson.—At a meeting of the executive council of the American Electro-therapeutic Association the following resolutions on the death of Dr. William F. Hutchinson, of Providence, R. I., were unanimously adopted:

Whereas, It becomes our painful duty to announce the death of Dr. William F. Hutchinson, one of the foundation fellows of the American Electro-therapeutic Association, as well as the first vice-president of the same; and

Whereas, In his death we lose a warm and faithful friend, a valued associate, and an accomplished member of the profession; therefore be it

Resolved, That this association desires to place on record its appreciation of his genial spirit, his active co-operation in the work of the association, and his deep interest in the scientific questions relative to his chosen profession.

Resolved, That we express our sincere regret and heartfelt sorrow at his death.

Resolved, That we tender to his sorrowing family an expression of our profound sympathy in their great loss.

Resolved, That a copy of these resolutions be sent to the bereaved family and to the medical journals and that they be spread upon the minutes of the association.

Original Communications.

ON THE ÆTIOLOGY OF APPENDICITIS.

By EUGENE HODENPYL, M. D.,

FIRST ASSISTANT IN PATHOLOGY,
COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA COLLEGE;
AND PATHOLOGIST TO ROOSEVELT HOSPITAL, NEW YORK.

WHILE the anatomy of the vermiform appendix, including its very many abnormal positions, has been recently carefully investigated by Bryant (1), Turner (2), Clado (3), and others, and while the surgical aspects of appendicitis have been very extensively written about, comparatively little has been done on its ætiology. This article records the observations that I have made in eleven cases. At the suggestion of Dr. McBurney, I have made bacteriological studies on the exudates which have occurred in some of the cases recently operated on by him. At the same time, I have studied various atypical forms and positions of the appendix which seem to have an important bearing in the ætiology of appendicitis.*

Bacterial Factors.—At the time these studies were undertaken there were few reported bacteriological observations on appendicitis; but recently I have found records of bacteriological examinations which have been made in twenty-four cases. Of these twenty-four cases, two were reported by Welch (4), one by Robb (5), three by Clado (3), four by Adenot (6), one by Fraenkel (7), one by Malvoz (8), four by Ekehorn (9), and eight by Fowler. In each of these cases the *Bacillus coli communis* was found in the exudate, and was not associated with any other species except in one of Welch's cases, in which a streptococcus alone was found, and in one of Fowler's, in which the *Bacillus pyogenes fetidus* was found in addition to the *Bacillus coli communis*.

THE WRITER'S STUDY.—1. *Technique.*—The exudate was collected by means of cotton swabs such as have been recently described and figured by Dr. Park (10). The swab consists of a bit of absorbent cotton wound on a steel rod four inches in length, the end having been previously roughened to prevent the cotton from slipping. The swab is put in an ordinary test tube plugged with cotton and the whole is thoroughly sterilized by dry heat. When thus prepared they may be kept indefinitely and ready for use in a clean jar. They may be conveniently carried as required in a small wooden box.†

The exudate was collected as soon as it came into view after the abdomen was opened and before the appendix was disturbed or the exudate subjected to contamination. The bacteriological examination was commenced in most

cases immediately thereafter, and in all cases within a few hours after the operation.*

2. *Description of the Cases examined by the Writer.*—CASE I.—October 13, 1892, man, aged twenty-one years, brought to the hospital almost moribund with general peritonitis. Operation soon after admission, but death occurred very soon thereafter. Autopsy, fifteen hours after death, showed general peritonitis, the cause of which was shown to be from extensive necrosis of the appendix. Nothing but the small ragged stump remained.

Bacteriological examination of a portion of the pus collected by a swab from the right iliac fossa showed *Bacillus coli communis* in pure culture.

FIG. 1.—Appendix of a new-born child with a very short mesentery.

CASE II.—Young woman; had been suffering from pain in the abdomen, fever, vomiting, prostration, etc., for about six weeks. The attack came on suddenly, but after two weeks greatly improved; but the symptoms again reappeared after a few days. Patient died soon after admission to the hospital without operation. Autopsy, nine hours after death, showed extensive inflammation and necrosis of the appendix, a large sinus behind the ascending colon filled with pus, and a large abscess of the right lobe of the liver. Bacteriological examination, from the pus about the appendix and from the abscess of the liver, showed in both *Bacillus coli communis* in pure culture.

CASE III.—November 10, 1892. Pus from a case of acute appendicitis occurring in Dr. McBurney's private practice. Bacteriological examination of the exudate showed *Bacillus coli communis* in pure cultures.

CASE V.—November 26, 1892, man, aged forty years; first attack of an acute appendicitis operated upon on the twelfth day of the disease. Large abscess with well-marked fecal odor; appendix not found.† Bacteriological examination: cultivations from the abscess showed *Bacillus coli communis* in pure culture.

* In each case stained cover slips were prepared from the swabs and glycerin-agar and gelatin plates were made.

† Bacteriological examination: culture from the exudate showed nothing but *Bacillus coli communis*.

* One of the cases was kindly furnished me by Dr. Park, two were found at autopsy, while the remainder were in persons operated on by Dr. McBurney, and I wish to offer him my thanks for the material which he kindly placed at my disposal.

† This method of collecting fluid material for bacteriological work, which was originally suggested by Prudden, has proved so eminently satisfactory in this, as well as along other lines of investigation, that its use during surgical operations and post-mortem examinations can be thoroughly recommended.

CASE VI.—December 12, 1892, woman, aged nineteen years; first attack of acute appendicitis operated upon on the fifth day. Appendix was perforated at the tip and was surrounded by an abscess shut off from the general peritoneal cavity. Bacteriological examination of exudate and contents of the appendix showed in both the *Bacillus coli communis* and the *Streptococcus pyogenes*.

CASE VII.—January 7, 1893, man, aged thirty years. History of repeated attacks of appendicitis. At the operation about twenty ounces of pus was found about the appendix, which was gangrenous. Bacteriological examination showed *Bacillus coli communis* in pure culture.

CASE VIII.—January 23, 1893, man, aged thirty-eight years; operation during third attack of appendicitis. Present attack lasted three days. About an ounce of foul-smelling pus surrounded the appendix, which showed commencing gangrene near the base. Bacteriological examination of cultures from the exudate showed nothing but the *Bacillus coli communis*.

CASE IX.—February 4, 1893, man, aged twenty-two years. Appendicitis of three weeks' duration. There was a large abscess, but the appendix was not found.* Bacteriological examination: *Bacillus coli communis* was found in the abscess in pure culture.

FIG. 2.—Appendix of a child three days old, sharply curved upon itself and bound down by adhesions.

CASE X.—February 17, 1893, boy, aged ten years; appendicitis of seven days' duration. First attack. There was perforation of the appendix and a large abscess extending as high up as the liver. Bacteriological examination: exudate contained *Bacillus coli communis* in pure culture.

CASE XI.—March 28, 1892, girl, aged ten years. First attack of appendicitis; operation on the ninth day. There was a very large abscess; appendix not found. Bacteriological examination: cultures from the abscess were *Bacillus coli communis* in pure culture.

Résumé of all the Bacterial Studies.—With the twenty-four cases of exudative appendicitis already referred to above and my own eleven cases, we have now thirty-five in all in which a bacteriological examination of the exudate has been made. In thirty-two of the thirty-five cases the *Bacillus coli communis* was the only germ isolated. In

some cases we have found in the walls of the appendix, and surrounded by exudate, colonies of this germ. In one case a few colonies of the streptococcus developed in association with this bacterium. In one case the streptococcus was the only species found. These streptococci corresponded in biological characters with the *Streptococcus pyogenes*. In one case the *Bacillus pyogenes foetidus* was found in addition to the *Bacillus coli communis*.

Significance of the Bacillus Coli Communis in the Exudation of Appendicitis.—The diagnosis of this bacillus, notably from the *Bacillus typhosus*, has received much attention of late from many observers; and those interested in this matter should consult the elaborate monograph of Wurtz (11). I shall not in this connection recount the many biological characters of this so-called "colon bacillus," nor enter here into the question of the possible multiplicity of varieties which this germ is believed by many to present. In my studies the variations were so slight that I regarded them as within the limits of the well-known biological characters of the *Bacillus coli communis* by which the germ is recognized in artificial culture media.

The question now arises as to the significance of the *Bacillus coli communis* in the aetiology of these cases of appendicitis. It is a natural inhabitant of the intestine. Can its presence in the exudate outside of the intestine be regarded as proving that it caused the lesion, or may it be in these cases but a secondary or adventitious or unimportant factor? In order to understand its exact significance it is necessary that we study most carefully certain facts concerning the bacillus itself.

These facts bearing on the significance of the *Bacillus coli communis* in these cases may be conveniently arranged into several groups—i. e., facts concerning—

1. The species of bacteria inhabiting the normal and diseased appendix.
2. The presence of bacteria in the normal abdominal cavity.
3. The pathogenic power of the *Bacillus coli communis*, including its difference in virulence when obtained from different sources.

1. *Bacterial Contents of the Normal and Diseased Appendix.*—In five cases gelatin and agar plates were made from the contents of normal appendices. In fifteen cases cultivations were made from appendices the seat of acute exudative inflammation.* In every one of these twenty cases, except one case (VI), the *Bacillus coli communis* was obtained in pure culture (nothing else grew). In Case VI, as has been already stated, associated with the *Bacillus coli communis*, both in the abscess and in the interior of the appendix, a moderate number of colonies of *Streptococcus pyogenes* developed.

In a single additional case the contents of an appendix of a stillborn child gave, in the cultures, a negative result. This observation is in accord with those of Escherich (12), who has found that the *Bacillus coli communis* does not begin to appear in the human intestinal tract until birth or until nursing has begun.

* Eleven of these cases are those just described; the remainder are cases of appendicitis in which the exudate was confined to the lumen of the appendix.

* In certain cases it was not thought advisable to make a very extended search for the appendix during the operation for fear of disturbing the delicate adhesions separating the abscess from the general abdominal cavity.

Cultivations were made in a number of instances from the contents of the healthy intestines and from healthy faeces, and in each a pure culture of *Bacillus coli communis* was the result. While a considerable number of different species of bacteria have been found in the healthy intestines, this bacterium occurs so very much more abundantly that it is frequently the only species obtained on cultivation.

2. *Concerning the Presence of Bacteria in the Normal Abdominal Cavity.*—In ten cases cultivations were made of material collected by the swab from the normal abdominal cavity in the region of the appendix after death from a variety of causes.

The autopsies were made at periods varying from one to twenty-two hours after death. In nine of the ten cases the result was negative; nothing grew in the cultures. In one case, from an autopsy made twenty-two hours after death, a few colonies of *Bacillus coli communis* developed. Wurtz and Hermann (13) and Welch (4) have found that after death, or at least after decomposition has fairly commenced, *Bacillus coli communis* may become widely distributed. Thus this bacterium has been found in post-mortem examinations in the heart's blood, liver, spleen, kidneys, etc., unassociated with lesions.

3. *The Pathogenic Power of Bacillus Coli Communis.*—The evidence that the germ is capable of being the cause of morbid process in various parts of the body is of two kinds: (a) Its occurrence in connection with lesions unassociated with any other micro-organism; and (b) the result of experiments on animals with the pure culture of the germ.

I examined two cases of general peritonitis following perforation—one of the stomach, the other of the intestine—and obtained on cultivation the "colon bacillus" in pure culture. In one case of peritonitis of unknown origin I found *Streptococcus pyogenes* in pure culture. In four cases of peritonitis following suppurative salpingitis I found in one the streptococcus, in the three others the *Staphylococcus pyogenes aureus*. In three cases of chronic salpingitis, without peritonitis, no bacteria of any kind developed in the cultures. While the results of these observations are too few in number to establish an absolute rule, yet they bear out the general belief, notably held by Welch, that the occurrence of the *Bacillus coli communis* in inflammatory exudations indicates a primary lesion of the intestines.

The number of cases recorded by others in which this bacillus has been found in connection with many pathological conditions is so large that it seems necessary to refer only to some of the more important. Veillon and Jayle (14) found the bacterium in pure culture in a dysenteric abscess of the liver. Barbacci (15) found it in pure culture in six cases of general exudative peritonitis following perforation of the intestine, and in one case of perityphlitic abscess.

Malvoz (8) found it in six cases of general exudative peritonitis following intestinal perforation. His cultures were obtained post mortem. All were made within thirty hours after death, and in all of his cases this was the only species found.

Muscattello (16) reports a case of perirectal abscess which

contained *Bacillus coli communis* in pure culture, which, when inoculated subcutaneously into guinea-pigs, resulted in abscesses containing thick, white, stinking pus, from which the bacillus was again obtained in pure culture.

Marfan and Leon (17), in two cases of death from ulcerative colitis, found this bacillus in all the organs.

Laurelle (18) found in two cases of peritonitis caused by perforation of strangulated crural hernia the colon bacillus in each.

In both cases the autopsies were made within five hours after death.

Gilbert and Girode (19) record two cases of suppurative inflammation of the gall bladder, which contained in each case the bacillus in pure culture.

FIG. 3.—Appendix of a child eleven days old. It is adherent throughout its entire length and sharply bent at its lower end.

Welch (4) has found it also in pure culture in three cases of peritonitis due to ulceration of the intestines, but without perforation; also in one case of ovarian abscess adherent to an ulcerated cancer of the rectum. Welch also states that he has only found *Bacillus coli communis* twice in other viscera in which there was no demonstrable lesion of the intestines.

Rossi-Doria (20) examined twenty fatal cases of epidemic diarrhoea of children. The autopsies were performed usually within twelve hours after death, and never later than twenty hours. Cultures were made regularly from the liver, spleen, kidney, and the enlarged lymphatic lymph nodes. These all showed the presence of the colon bacillus. Wyss (21) found it in a very severe case of catarrhal enteritis in the liver, spleen, kidney, Peyer's patches, and mesenteric lymph nodes.

A. Fraenkel (22) examined thirty-one cases of peritonitis from various causes, and in nine of them found the *Bacillus coli communis* in pure culture; and of these cases, all were accompanied with intestinal lesions.

Cases of acute meningitis in which the germ has been isolated have been described by Neumann and Schaeffer, Roux, Adenot, Netter, Balp, and Sevestre and Gaston. It has also been found in cases of ulcerative malignant endocarditis by Netter and Martha, in thyreoiditis by Tavel, in cystitis by Clado, Achard, Rodet, Roosing, and many others. It has been found in a case of suppurative arthritis by Sevestre and Gaston. For a detailed description of these cases of meningitis, endocarditis, cystitis, and arthritis, consult the monograph of Maicaigne (23).

FIG. 4.—Adult appendix, six inches in length: pervious throughout, but firmly adherent to the gut and covered over with delicate adhesions.

It is noteworthy that in a large majority of the foregoing cases in which the colon bacillus has been found in the inflammatory exudate, in other situations, outside the intestines, there have been destructive lesions of the intestinal wall. Indeed, the presence of this bacillus in other regions of the body seems to be almost always associated with intestinal lesions.

The presence of this bacillus in the general abdominal cavity is to be expected where there is perforation of the intestines; ulceration of the intestinal wall, of course, facilitating the escape of the germ. Certain malpositions and structural changes in the gut facilitate the escape of bacteria through the intestinal wall, without either ulceration or perforation, as has been shown by Maicaigne (23), who found the colon bacillus in the sac in cases of strangulated hernia. Recently Arnd (24) has demonstrated the escape of bacteria through the wall of the gut experimentally in rabbits. According to Arnd, who experimented especially with the *Bacillus pyocyaneus* and *Bacillus prodigiosus*, if a portion of a rabbit's intestine be constricted by means of a rubber band,

bacteria pass rapidly through the wall as soon as stasis has been induced in the blood-vessels of the constricted gut. Furthermore, Clado (3) professes to have demonstrated the passage of *Bacillus coli communis* through the wall of a strictured appendix without perforation or ulceration.

It will be noticed from the above recorded cases that the *Bacillus coli communis* has been more often found in the exudate of peritonitis than in exudative inflammation elsewhere. It has long been known that sterilized faeces, etc., when thrown into the peritoneal cavities of animals in reasonable amounts usually do no harm. When, however, certain living micro-organisms escape through the wall of the gut, either with or without a solution of continuity, inflammation is at once produced. If now, in addition to the facts already adduced, we are able to prove experimentally that the germ possesses pathogenic properties, we shall then have strong evidence that this bacterium was actually the cause of the inflammation in the cases just referred to.

(b) *Results of Inoculation Experiments in Animals with Pure Cultures of Bacillus Coli Communis.*—Escherich (12), who first described the germ, found that its inoculation in mice gave negative results. In guinea-pigs sometimes no lesions followed its inoculation, but more often abscesses developed at the site of inoculation. Intravenous injection was usually followed by death within twenty-four hours, with intense catarrhal lesions of the intestines, swollen Peyer's patches, etc. There was also usually intense congestion of the peritonæum, with bloody fluid in the peritoneal cavity. The germ was found in the blood and throughout the solid viscera.

Laurelle (18) found that *Bacillus coli communis*, suspended in salt solution, when inoculated into the peritoneal cavity, gave negative results. When, however, the germ was suspended in simple sterilized water, or mixed with ox gall, etc., the animals died quickly, with intense peritonitis. He also found that neither the sterilized water nor the ox gall alone would cause peritonitis when injected into the abdominal cavity. Blackstein (25), Gilbert and Girode, and many others have demonstrated the pathogenic power of *Bacillus coli communis*, abscesses, sepsis, etc., having usually followed its inoculation; but it has been noticed that the results obtained by different observers have seemed to vary within rather wide limits.

The differences which have been observed in the results after inoculation appear to have depended upon the difference in dose, species of animal used, the nature of the inoculation, whether subcutaneous, intraperitoneal, or intravenous, and especially upon the age of the culture and the source from which it was obtained—i. e., from faeces or from inflammatory exudates. Formerly the difference in the results obtained after inoculation of animals with pure cultures of bacteria was ascribed largely, if not entirely (the dose and the other conditions being the same), to the difference in susceptibility of the animals. Latterly we have begun to learn more of the difference in virulence in the bacteria themselves. Since Pasteur first showed that the virulence of the *Bacillus anthracis* could be very markedly altered by slight variations in the temperature at which the germ was grown, it has been observed that with

many other species of bacteria we are able to alter, within certain limits, not only the degree of virulence, but other biological characters as well. It has been claimed, notably by Maicaigne (23), that *Bacillus coli communis* obtained from healthy intestines is very decidedly less virulent than when obtained from lesions in the production of which it is presumably the cause. He also makes the very interesting observation that there is a decided difference in virulence of cultures from healthy faeces and from diarrheal stools. This last observation, if confirmed, will throw an important light on the aetiology of certain of the intestinal lesions. Ekborn (9) likewise has observed a very great difference in the virulence of cultures obtained from the exudate in different cases of appendicitis. In one case they were obtained during an acute attack with perforation, suppuration, etc., and were found when inoculated into animals to be exceedingly virulent. Other cultures were obtained from a milder case which was operated on during the quiescent stage, and in these the virulence was much less marked.

It has been observed, as in the case with many other species, that the virulence of *Bacillus coli communis* becomes attenuated by long cultivation on artificial culture media. Experiments now going on in the Laboratory of the College of Physicians and Surgeons, and shortly to be published by Dr. Alexander Lambert, confirm the view that the germ obtained from faeces is less virulent than those obtained from pathological lesions of which they were presumably the cause.

It is evident from the facts now brought forward that, while the *Bacillus coli communis* under normal conditions in the gut is harmless, it may become pathogenic when placed under abnormal conditions—*e. g.*, outside the intestinal canal. Different specimens of the germ may not all be of the same degree of virulence; and there is some evidence that those obtained from inflammatory exudates are more virulent than those obtained from natural sources.

We as yet know but little of the exact conditions under which the virulence of this germ may become increased or diminished. A change in its situation in the body may perhaps effect changes in its pathogenic powers. This change in situation appears to be of most frequent occurrence in the appendix. It will be seen later that very frequently its lumen becomes more or less occluded, when, if the occlusion be sufficiently complete, the pressure of its confined contents may force the bacillus into the tissues and through its wall.

Recapitulation.—1. The *Bacillus coli communis* is normally present in the intestinal canal after birth, but it is never found during life outside the intestinal canal in any of the other viscera, so far as is known, without being accompanied by lesions.

2. We have seen that the *Bacillus coli communis* has been found in the exudate in thirty-four out of thirty-five cases of exudative appendicitis, and in thirty-one of these it was found unassociated with any other germ.

3. The *Bacillus coli communis* has been found as the only species of bacteria in connection with a variety of inflammatory and necrotic conditions other than appendicitis.

These have almost always been associated with a demonstrable lesion of the intestinal wall, and there is evidence that under certain conditions the germ may pass through the intestinal wall without a solution of continuity. It has been abundantly shown that the germ is highly pyogenic.

4. Inoculations into animals of pure cultures of this bacillus result in inflammation, in the formation of abscesses, and sometimes produce general septic infection or intoxication.

It seems that in exceptional cases the disease may be caused by the ordinary "*pyogenic bacteria*"—*i. e.*, the *Streptococcus pyogenes*, and the *Staphylococcus pyogenes aureus*, etc., as well as by the bacterium just considered. We have the record of one case in which the *Streptococcus pyogenes* was the only species isolated from the exudate.

FIG. 5.—Adult appendix, showing a twist in the middle portion resulting in atrophy of the lower half, which is also adherent.

Other Probable Factors in the Production of Appendicitis.—In addition, there may be still other contributing if not direct factors in the production of appendicitis. It is said to have been caused by *actinomyces*; but as yet I have not been able to find a single case reported in which *actinomyces* have been actually found in disease of the vermiform. At any rate, its occurrence is of such great rarity that it may be regarded more as a pathological curiosity than as an aetiological factor in appendicitis. *Tubercular* and *typhoid ulcers* sometimes may be associated with appendicitis. Tubercular and typhoid ulceration of the vermiform appendix is not an uncommon occurrence in tuberculosis of the intestinal canal and in the course of typhoid fever. It is rarely, however, that either of these conditions are found in connection with that

group of symptoms and physical signs indicative of appendicitis. In none of my cases have I found tubercular or typhoid ulcers of the appendix, and indeed, while they are commonly held as being sometimes the cause, yet there are but few actual cases recorded. I may mention, in passing, the remarkable fact that typhoid, and especially tubercular ulcers of the intestinal tract, as is frequently the case with many other morbid processes, often bear no very proportionate relation to the severity of the physical symptoms. Tubercular ulcers of the intestine, and even extensive tubercular peritonitis, often give rise to almost no discomfort, and so similar lesions of the appendix are usually unattended by the usual indications of disease of this organ.

Concretions of various kinds blocking up the lumen of the canal were formerly regarded as the usual cause of appendicitis; but this view has since been largely abandoned by surgeons, although it continues to be the theory generally held by the laity. Fitz (26), in an analysis of some three hundred cases of appendicitis, found concretions in but five per cent., and Ribbert (27) found them thirty-eight times in four hundred autopsies, or about ten per cent. in persons with presumably normal appendices. Of these thirty-eight cases, there were twenty with more than one concretion—viz., four with two, eight with three, three with four, five with five. It can readily be conceived that a concretion when of large size or irregular shape may cause irritation or interference with the proper circulation and secretion of the appendix. The result of such interference may be sufficient to so alter the integrity of the mucous membrane as to allow of the escape of the bacterial contents into the tissues. In two of my cases of appendicitis concretions were found the pressure from which had caused ulceration, with perforation in one.

FIG. 6.—Adult appendix, bent at an acute angle, adherent throughout, and entirely cut off from the peritoneal cavity by adhesions passing over it.

Certain Anomalous Conditions of the Appendix, and their Relations to Appendicitis.—It seems to be an opinion widely held among surgeons that a large proportion of the cases of acute exudative appendicitis are associated with a more or less complete occlusion of the lumen of the appendix. In the cases which I have examined I have nearly always found an old stricture in the appendix.

We may get some light on the origin of this condition if we will but study certain peculiar forms of its development, arrangement, and evolution. It is generally conceded that the vermiform appendix, like the wisdom tooth, is gradually undergoing retrograde evolution, and it seems to be a fact that such organs are very prone to undergo inflammatory changes. In the case of the wisdom tooth, for instance, it is either altogether wanting, rudimentary, or, when present, often is the seat of inflammation. There seems to be no other structure in the body which, from its first differentiation, shows so many departures from the established norm as the appendix.

FIG. 7.—Adult appendix, bent at an acute angle, and also showing a twist in the middle portion, partially covered by adhesions.

When the appendix first begins to be differentiated from the cæcum, about the fifth or sixth month, it is situated at the center of what is to be the most dependent portion of the cæcum. At this time the cæcum is lying almost transversely high up in the abdominal cavity, with the appendix just beneath the liver. As the cæcum descends toward the right iliac fossa the external lateral portion develops more than the internal, consequently the appendix approaches the internal border. At birth, and for some little time thereafter, the base of the appendix is distinctly funnel shaped. As development proceeds, its dilated opening gradually grows smaller until adult age, when the cæcal orifice is somewhat smaller than the rest of the lumen of the appendix. Very frequently the lumen at this point is markedly constricted, and it is just at this point—viz., at the cæcal opening—that strictures of the appendix are, it seems, most often found in appendicitis.

Partial or complete occlusion of the lumen of the appendix is of very frequent occurrence in presumably healthy persons. Ribbert (27) found strictures ninety-nine times in his four hundred autopsies, or in twenty-five per cent. With regard to the age in which he found this condition, Ribbert gives the following: One to ten years, four per cent.; ten to twenty years, eleven per cent.; twenty to thirty years, seventeen per cent.; thirty to forty years, twenty-five per cent.; forty to fifty years, twenty-seven per cent.; fifty to sixty years, thirty-six per cent.; sixty to seventy years, fifty-three per cent.; seventy to eighty years, fifty-eight per cent. He did not observe them in children under five years. It has, however, been observed a number of times in the fetus, and I have twice seen strictured appendices in new-born children. Ribbert did not find total obliteration of the appendix under thirty years of age,

separate bands. These bands, like all fibrous-tissue adhesions, tend to contract and become shorter, so kinks, twists, of actual occlusions are produced. Hand in hand with the production of adhesions and the formation of strictures, the appendicitis itself tends to undergo atrophy. In Photograph No. 10 it will be seen that the appendix is shut off from the peritoneal cavity and is, in addition, completely obliterated, having dwindled into a slender fibrous cord.

Histological examination of these strictured appendices shows varying degrees of atrophy of the mucous membrane, and at the strictured point an absence of the mucous follicles and lymphoid nodules.

While the majority of cases of acute exudative appendicitis are associated with more or less complete stricture, there are yet other cases in which none exist. Indeed,

FIG. 8.—Adult appendix, bent in three places by connective-tissue adhesions. Adherent in parts.

but between the ages of sixty and seventy years he found it nine times in four hundred autopsies. The precise cause of this condition is not entirely clear. Fitz (26) and Birr-hoff (28) regard it as pathological. On the other hand, Ribbert takes the ground that while strictures are sometimes probably the result of former inflammatory processes, the majority are probably examples of partial retrograde evolution. With the latter opinion I entirely concur.

The accompanying series of photographs show some of the more common atypical forms of the appendix which I have found at autopsies, and illustrate the kinks and strictures. In none of my cases have I been able to find evidences of recent inflammation. We find the mesentery or mesocolon generally shortened or entirely wanting, so that the appendix becomes firmly attached to the neighboring parts or is adherent except at its tip. In addition we find delicate adhesions passing over the peritoneal surface sometimes evenly, and completely shutting it off from the general peritoneal cavity. (See photographs Nos. 4 and 6.) More commonly the adhesions are arranged in

these are sometimes of the most severe type. In some the appendix, almost from the very onset of the disease, may become gangrenous, but as yet I have not had an opportunity of examining such a specimen, and am consequently unable at this time to account for their occurrence.

The length of the appendix varies within wide limits, and this too seems to have a bearing on its retrograde evolution as well as on the ætiology of appendicitis. The longer the appendix, other things being equal, the more liable it is to inflammatory changes. In Ribbert's four hundred cases he finds the length varied from $2\frac{1}{2}$ ctm. to 21 ctm. Occasionally appendices are met with having even a greater length than 21 ctm. Also the length of the appendix varies considerably at different periods of life. Ribbert finds that the average absolute length at birth is $3\frac{3}{8}$ ctm.; up to five years, it is $7\frac{3}{8}$ ctm.; between five and ten years, it is 9 ctm.; between ten and twenty years, it is $9\frac{3}{4}$ ctm.; between twenty and thirty years, it is $9\frac{1}{2}$ ctm.; between thirty and forty years, it is $8\frac{3}{4}$ ctm.; between forty and sixty years, it is $8\frac{1}{2}$ ctm.; over sixty

years, it is $8\frac{1}{2}$ cm. Thus we see that the appendix reaches its greatest maximum length in early adult life, after which it tends to become shorter. It has also been noted that the relative length is much greater in infants than in adults. In the new-born, compared with the length of the large intestine, Ribbert estimates it to be 1 to 10, while in the adult it is 1 to 20.

FIG. 9.—Adult appendix, short and dilated, which was entirely concealed between folds of intestine, where it was firmly bound down by adhesions and shut off from the general peritoneal cavity.

Whether these atypical forms of the appendix are to be regarded as of pathological origin, or as examples of retrograde evolution, although exceedingly interesting from a biological standpoint, is a matter of no practical importance. The fact is that there is no other portion of the alimentary canal which is so exceedingly liable to become the seat of exudative inflammation.

Conclusions.—It is evident from these studies that several factors must be taken into account in considering the etiology of appendicitis. In the first place, the vermiform appendix of very many individuals is an especially vulnerable region of the intestinal tract, because it is especially liable to attacks of acute exudative inflammation. Thus strictures, either the result of old inflammation or the result of retrograde evolution; adhesions, drawing the appendix into abnormal positions, producing kinks, twists, etc., of its lumen; ulceration, from whatever cause; atrophy of the mucous membrane, concretions, and malpositions—may apparently act as predisposing causes in appendicitis. Such altered conditions may interfere with the integrity of the walls of the appendix, either by thinning of the wall from distention of the canal, or by interference with the nutrition of the wall from disturbances of circulation, or by the presence of concretions in the lumen, or by atrophy of the mucous membrane. By these means the escape into the tissues of bacteria, which the appendix constantly harbors or may occasionally contain, is probably facilitated. The studies thus far made indicate that the bacterium most

frequently isolated is the *Bacillus coli communis*. This, as we have seen, is harmless in its natural habitation, but there is evidence to show that it becomes distinctly pathogenic when it escapes into the tissues or into situations where it does not naturally belong. At the same time the possible occurrence of the *Streptococcus pyogenes aureus* should not be ignored.

But, while the facts at our disposal at this stage of our knowledge would seem to point toward the *Bacillus coli communis* as a most important factor in the causation of acute appendicitis, several observations made on this germ, as well as upon the causation of perforating peritonitis not associated with lesions of the appendix, tend to warn one against forming too hasty or sweeping conclusions, for the following reasons: 1. The *Bacillus coli communis* is a germ which under ordinary conditions grows with extreme rapidity in cultures, and may thus conceal more slowly growing and less conspicuous forms. Barbacci (30), whose studies had not reached me until my own were completed, for example, has shown that in a considerable number of cases of perforative peritonitis in which cultures gave a growth of *Bacillus coli communis* alone, inoculations of the original exudate into mice revealed the presence in it of the pneumococcus.

My own studies, here recorded, did not embrace this unusual and more delicate technical procedure, because at the time they were made the reason for it was not obvious, so that, while there are no special grounds for believing that any other germs were overlooked with the technique which I have employed in common with most of those who have been engaged in such studies, the remote possibility is one which should be considered in this connection.

FIG. 10.—Appendix which has been converted into a slender, fibrous cord. There is no lumen, and it is completely invested by adhesions.

In the second place, it should not be forgotten that in perforation of the appendix, as in the perforations of the gut, other things than living germs may gain access to

the peritoneal cavity. These may be either inert solid material from faeces, or most complex and little-understood chemical substances, or the bodies of dead germs, which, as is well known, are present in large numbers in the faeces. The possible significance of these materials, other than living bacteria, which may escape from the appendix with the latter, in perforation or in abnormal permeability of the wall from whatever cause, will be evident to those who have followed the recent researches in many directions which show how greatly the effects of various germs in the tissues are enhanced by their association with various chemical substances whether introduced with the bacteria or preceding or following them. Extremely important in this connection are the studies of Barbacci on perforative peritonitis, already alluded to. He finds that the introduction of the *Bacillus coli communis* alone into the peritoneal cavity of animals does not induce a lesion which is fairly comparable with perforative peritonitis, and that therefore other factors must be involved. The necessity for seeking these other factors is more distinctly emphasized by Barbacci than by other experimenters on the action of the *Bacillus coli communis* in the peritoneal cavity. As a result of a series of ingenious and interesting experiments which the scope of this paper does not permit me to recount, Barbacci concludes that perforative peritonitis is the result of three factors:

1. The escape of faeces and intestinal gases into the peritoneal cavity.
2. The development of bacteria therein.
3. The constant irritation resulting from the continued escape of intestinal contents.

While these experiments of Barbacci's are important and suggestive, they need the control of repetition and very large extension before we shall understand the exact nature and full significance of these factors which re-enforce the action of the bacteria, but they are precise enough, even now, to emphasize the necessity of caution in attributing to the *Bacillus coli communis* a too exclusive rôle in the aetiology of the peritoneal inflammations accompanying acute appendicitis.

It is in a measure assumed in this paper that the inciting cause or causes are in part or largely identical with those which incite the acute inflammation in the wall of the appendix itself. The evidence that this assumption is correct and the gathering of data upon the commencement of the inflammatory processes in the wall of the appendix itself before the peritonæum becomes involved, as well as the exact relationship between malpositions and chronic lesions of the appendix and the acute processes, are matters for future investigations.

We have, therefore, two classes of factors in the causation of acute appendicitis: 1. Predisposing factors, which may vary in different cases. 2. More active factors, of which there seem to be two distinct but intimately associated elements: *a*, bacterial; *b*, the less well defined and less understood chemical factors associated with the unorganized faecal contents.

While several species of bacteria may, as it would appear, play an important and perhaps predominant rôle in

inciting the acute exudative inflammation in the wall of the appendix and in the peritonæum, there seems to me to be reason for the belief that the *Bacillus coli communis* is the most important.

RECURRENCE AT A NEW SITE OF A LARYNGEAL GROWTH (PAPILLOMA)

IN A CASE ALREADY REPORTED UNDER THE TITLE,
"EVULSION OF A LARYNGEAL TUMOR
WHICH RETURNED TWENTY-TWO YEARS AFTER ITS
REMOVAL BY LARYNGOTOMY."

WITH AN ANALYSIS OF THIRTY-FOUR CASES.*

By R. P. LINCOLN, M.D.

I AM encouraged to invite your attention for a few minutes to the following report by my conviction that subsequent histories of operations are often essential to enable

* Read before the American Laryngological Association at its fifteenth annual congress.

the surgeon to determine the best mode of treatment. Unfortunately, it too often happens that an ultimate history is not available when sought for, because not recorded. Were such data accessible our prognosis would be more definite, and consequently the patient and physician more in accord.

I beg, therefore, to offer a brief digest of the report of a case presented by myself to this association four years ago, a full report of which may be found in the *Transactions* of the eleventh annual meeting of this association. Illustrations of the original tumor, reproduced from a lithograph, and of the first recurrence, made from photographs, are embodied in the report. Following this I will furnish an account of a third growth springing from a point hitherto free from disease, and then attempt an analysis of thirty-four recorded cases.

Our subject is a lady who, in 1862, when twenty-three years of age, first experienced difficulty in her larynx. Two years later the late Dr. Elsberg demonstrated a tumor of large size extending below the vocal cords. "It was attached in front along a line across the whole epiglottis and the posterior parts of the vocal cords." The growth, in bulk amounting to a "small egg," was removed by forceps and the base cauterized with acid nitrate of mercury. The result of treatment was not permanent. The tumor reproduced itself and necessitated further operation. In 1867 Dr. Elsberg performed laryngotomy and completely eradicated the growth.

The patient remained free from any symptom of trouble for twenty-two years. In January, 1889, I first saw her, when I found "a tumor of about the size of a large kernel of corn growing from the posterior third of the right vocal cord. The tumor was of a light pink color and resembled an ordinary papilloma." Our fellow, Dr. French, made a photograph of the larynx and its contents. On May 24, 1889, the whole of the tumor was removed by Czuczo's forceps. A few days later the seat of the growth was thoroughly cauterized with the galvano-cautery. The pathologist, Dr. Ferguson, examined a specimen of the tumor and pronounced it a simple papilloma, and not likely to return. After the recovery from the effects of the operation in 1889 the patient enjoyed a good speaking voice and freedom from hoarseness, in fact no inconvenience from the vocal organ, until the past winter, when a steadily increasing hoarseness led her to again consult me. An examination revealed a new development of growth, not where I expected to find it, but springing from the left vocal cord anteriorly, near the commissure. It was a little more than half as large as that removed four years ago. Though smaller than its predecessor, it caused greater inconvenience, probably from its positions the patient often experiencing suffocative attacks, due apparently to spasm of the glottis. Coughing, too, was very harassing. Intolerance expresses the condition. On April 20th the tumor was removed with the same facility and by the same method as already described in the previous treatment. The relief of all symptoms was more immediate. The microscopic character of the growth was identical with that of the former.

In connection with this case I have thought it would be interesting to tabulate all the cases of laryngeal papilloma recurring after operation that I could find in medical literature, and after a very hurried search I have succeeded in collecting thirty-four, including the one just narrated.

Among the questions naturally arising from a study of these cases are the following: Does this table harmonize

with the present views of pathologists in regard to the recurrence of benign tumors? Does the result of the operations indicate that the methods employed are defective in completely eradicating the neoplasm, or is the inference that there is in some individuals an inherent tendency to the development of morbid growths, such as papillomata?

In Heath's excellent *Dictionary of Practical Surgery*,* which is designed to present a compendium of the latest accepted opinions on the subjects of which it treats, Mr. Alfred Willett makes the following comprehensive statement in regard to the subject of recurrence: "Non-malignant tumors are seldom reproduced, and one is tempted to say never, if the whole of the visible growth has been removed." That this is altogether too sweeping an assertion as regards laryngeal papillomata, many of the cases in the table would seem to clearly indicate. In a considerable proportion of instances there can be no question that some portion of the neoplasm remained after operation. This is expressly stated to be the fact in Cases 2 (Fauvel), 4 (Fauvel), 11 (Fauvel), 12 (Mackenzie), 18 (Fauvel), and 23 (Lennox Browne). In others, notably mine (2) and one of Mackenzie's (14), the fresh growths were entirely on new sites, and can not therefore be strictly called recurrences. Excluding these two classes of cases, there remain a certain number of cases in which, although complete eradication was effected, a recurrence proper of the tumor took place on the original site. In some instances—as in Cases 24 (Lennox Browne), 26 (J. H. White), and 27 (Eliasberg)—the fresh growths occurred both in the former situations and in new ones.

"It is an altogether different thing," says Felix Semon,† "whether from the same place from which a papilloma has just been removed a fresh one springs up, or whether after the removal of a papilloma from the anterior commissure of the vocal cords another one begins to grow from one of the laryngeal ventricles. The latter event is evidently no 'recurrence' in the proper sense of the word, though often wrongly thus denominated, but evidence of a tendency to general papillomatous degeneration."

As to the likelihood of recurrence of papilloma after extirpation, remarks Sajous,‡ the following rules, according to Paul Bruns and Oertel (quoted from Morell Mackenzie), who divided papilloma into three classes, may furnish an approximate idea.

First Class.—Light-red or dark tumors, varying in size from a millet seed to a bean, with uneven surface and broad base, sometimes solitary, but generally thinly scattered and never numerous, either do not recur at all or only after some months.

Second Class.—Whitish-gray, exquisitely papillary, warty, or conical tumors, nearly always originating with a broad base from the vocal bands in adult patients, also recur very slowly, often not till after several years.

Third Class.—Large reddish tumors resembling a mulberry or cauliflower. They may be solitary, but are most

* Vol. ii, p. 681.

† Heath's *Dictionary of Practical Surgery*, vol. i, p. 894.

‡ *Diseases of the Nose and Throat*, Philadelphia, 1886, p. 380.

frequently multiple, and are commonly seen in children. These generally recur after one or two months.

A strong confirmation of the correctness of these views in regard to the third class of papilloma mentioned is afforded by Cases 21 (Hooper), 26 (J. H. White), and 27 (Eliasberg).

As a rule, of course, in benign tumors, the more complete the extirpation, the greater will be the chance of immunity from recurrence. But whatever procedure may be adopted, and however perfectly the growth may be removed, there will be cases met with from time to time in which recurrence inevitably takes place. Why this should be so can probably be explained only on the hypothesis that in certain individuals there is an inherent tendency to the development of neoplasms on the mucous membranes. In regard to the ætiology of papilloma of the larynx Garel* gives his hearty assent to the opinion of Thost, that papilloma is not properly a tumor, but merely a proliferation of the mucous membrane, and that this proliferation will be produced, for example, under the direct irritation of the membrane due to purulent, viscid, or dry secretions such as one meets with in the various catarrhal affections.

The principal ætiological factor in the development of papilloma and other non-malignant growths in the larynx is assigned by various authorities (Fauvel,† Mackenzie,‡ Cohen,§ Lennox Browne,|| Semon,^ Sajous^) to be chronic hyperæmia of the mucous membrane. Says Lennox Browne,‡ for instance: "Without doubt the most common cause is hyperæmia, and naturally all which tends to excite congestion will predispose to the production of new formations. Catarrh, the use of the voice during catarrhal attacks, certain occupations accompanied by the inspiration of noxious vapors, may all be considered predisponents of laryngeal growths." Bosworth, so far as I am aware, is the only writer who maintains that a large majority of the cases develop in a perfectly healthy larynx, stating that, at all events, in most of those which have come under his own observation it was difficult to discover any existing inflammatory condition. Traumatism, however, in the form of laryngeal strain or overexertion of the voice, he acknowledges, is undoubtedly to be regarded as a not infrequent cause of the disease. That such laryngeal strain is ordinarily accompanied by more or less congestion of the mucous membrane would seem to be the experience of most observers.

But, granting that chronic hyperæmia, laryngeal strain, and various other sources of irritation are instrumental in the production of these neoplasms, this class of causes is evidently not sufficient to account entirely for their development, since there are vast numbers of individuals who suffer

from these and yet do not become affected with laryngeal tumors. We are forced, therefore, to the conclusion that in certain persons there is an inherent tendency to the production of such growths. Now if, after the removal of the neoplasm by operation, this tendency still exists, it would seem to be reasonable to suppose that, should favorable circumstances be present for its reproduction, the growth is liable to recur. In discussing the subject of recurrence after removal, Lennox Browne* expresses the opinion that such reproduction is much more frequent than is generally supposed, and that while this is sometimes due to the incompleteness of the operation, in others it results from a mucous membrane having a neoplastic proclivity.

Furthermore, in regard to laryngeal papilloma, there is some ground for the view held by Fauvel,† that certain persons appear to be the subjects of a special papillomatous diathesis. He states that it is not rare to find on the persons of those suffering from papilloma of the larynx similar warty growths on the skin or on other mucous membranes besides the laryngeal. In two of the cases cited in his work (Nos. 248 and 253), where a brother and sister were affected with papilloma of the vocal cords, he found that both the patients had warts upon the face and hands. In one or two of the cases in my table it is stated by those reporting them that the patient had warts on the hand, and, as we have seen, Semon‡ speaks of a "tendency to general papillomatous degeneration."

In regard to the matter of operation, experience would seem to show that the various approved methods of intralaryngeal procedure, if employed with skill, will ordinarily accomplish all that can be expected in this class of cases in the way of protecting the patient against a recurrence of the disease. It was formerly maintained that thyrotomy offered a more efficient means of eradicating the growth and securing future protection; but the statistics of Bruns,* of Tübingen, are considered by most of the best authorities to have proved these views to be unfounded. Thyrotomy should then be resorted to only under special circumstances, since, as has been said, it has been shown beyond question that in a certain proportion of cases recurrence will take place however perfectly the growth may have been extirpated.

Semon|| has found that if, in cases of multiple recurring papillomata, the intralaryngeal removal be perseveringly proceeded with, almost always, finally, a time arrives when the tendency to a fresh formation of these growths appears to become exhausted. His experience has been confirmed by others. In Case 8 (Fauvel), in the table, although a small portion of the growth still remained after evulsion and cauterization, the second recurrence did not take place until five years had elapsed, which, Fauvel believes, goes to show that, even in cases where the destruction is not complete, recurrence, if it ensues at all, may be

long delayed. In Case 21 (Hooper) repeated operations were performed for nearly a year (the growth in the meanwhile constantly recurring and at times spreading rapidly), when finally the process became arrested; and this notwithstanding the fact that portions of the neoplasm still remained in the larynx. In Case 23 (Lennox Browne) a small fragment of the growth was left, but the recurrence did not take place for two years and a half. In one instance of obstinate recurrence Lennox Browne states* that a good result was obtained from enjoining absolute silence for two months and the application during that period of continuous cold on the larynx by means of a Leiter coil.

It is interesting to note that in two of the cases in the table—26 (J. H. White) and 27 (Eliasberg)—spontaneous cure occurred after the performance of tracheotomy. Dr. White in his report† refers to four other similar cases—two by Oertel, quoted by Hoffmann (*Volkmann's Sammlung klin. Vorträge*, No. 315), one by G. Hunter Mackenzie (*Lancet*, April 6, 1889), and one by Garel (*Annales des maladies de l'oreille*, etc., June, 1891). He also calls

* *Op. cit.*, p. 44.

† *Journal of the American Medical Association*, October 22, 1892, p. 478.

attention to the opinion expressed by Thost (Ueber Papillen in der oberen Luftwegen, *Deut. med. Woch.*, May, 1890) that papilloma of the larynx in children will always disappear spontaneously if let alone; that it is a benign neoplasm and without danger. "If this is correct," he asks, "why should thyrotomy, with its attendant risks to life and voice, be performed? Is it not better to let such cases alone, merely keeping them under observation to guard against suffocation from any sudden or unusual excessive development?" It is only in these exceptional cases, he continues, that tracheotomy is called for, and it will be all the surgical interference required.

Finally, in our consideration of this table, it may be well to note the suggestive case (No. 31) in connection with which Lennox Browne directs the attention of the profession—for the first time, I believe—to the possibility of hypertrophy of the pharyngeal tonsil being an aetiological factor of laryngeal papillomata in children. Whether this be really the case or not, the fact remains that the patient, in whom rapid recurrence had taken place, recovered after the removal of adenoid vegetations which were found behind the soft palate. In any similar case it would certainly be advisable, as a possible precaution against recurrence, to adopt the same course.

No. of case.	Date.	Sex.	Age.	Occupation.	Situation and extent.	Treatment.	Operator.	Reference.	Time of recurrence.	Subsequent treatment; final result; remarks.
1	June, 1862.	F.	23	Attached in front along a line across the whole epiglottis, and passing below the vocal cords; of the size of a small hen's egg, and everywhere adherent to the parts beneath except in most dependent portions.	Removal with scissors, cutting forceps, and polypus forceps. Remnant cauterized with acid nitrate of mercury. Later, laryngotomy, without tracheotomy; complete removal of every vestige of the growth.	Louis Eleberg.	<i>Transactions of American Laryngological Association</i> , 1889, p. 141.	22 years.	Evislon with Czuczo's forceps, followed by application of galvanocautery, by Dr. R. P. Lincoln.
2	Sept., 1862.	M.	45	Manufacter.	Both vocal cords, covering nearly their entire length.	Evislon with Fauvel's forceps, and cauterization with chromic acid and nitrate of silver.	Ch. Fauvel.	<i>Maladies du larynx</i> , 1876, p. 277.	Within 1 year.	Patient returned to his home in the country before the growth was entirely removed. At different times new portions were taken away, and then the case was lost sight of. In 1867 the neoplasm was operated on by Bruns, of Tübingen, with the écoueur, and cauterizations with chromic acid; complete recovery.
3	April, 1863.	M.	44	Carpenter.	Almost the entire lining membrane of the larynx.	Evislon with tube forceps and application of escharotics.	Morell Mackenzie.	<i>The Use of the Laryngoscope</i> , 2d ed., p. 121; <i>Growth in the Larynx</i> , p. 315.	On both ventricular bands, March, 1870 (7 years).	Second series of operations with tube forceps; cure.
4	Jan., 1865.	M.	28	Clerk.	Free border of right vocal cord; of the size of a large pea.	Evislon with Fauvel's forceps.	Ch. Fauvel.	<i>Maladies du larynx</i> , p. 346.	1 year.	Patient left before complete destruction of the growth was effected. Evislon again practiced, with complete restoration of voice. Seven years and a half later patient returned with partial reproduction of the tumor.
5	Dec., 1865.	M.	39	Inn-keeper.	Anterior commissure and both vocal cords.	Evislon with crushing forceps.	Türk.	<i>Klinik der Kehlkopfkrankheiten</i> , p. 578.	Within 1 year.	Excision and cauterization; cure.
6	Feb., 1866.	M.	30	Employee in theater.	Right vocal cord; of the size of a pea.	Evislon with wire loop and application of chromic acid.	Ch. Fauvel.	<i>Maladies du larynx</i> , p. 366.	8 years.	Tumor again removed, and did not afterward return.
7	1867.	M.	45	Workman.	Multiple growths on free borders of both vocal cords and inferior surface of epiglottis, and in the angle of the thyroid cartilage.	Evislon with Fauvel's forceps.	Ch. Fauvel.	<i>Ibid.</i> , p. 418.	Within 6 months.	Neoplasms much larger and more numerous than before. Evislon and cauterization with chromic acid. Rapid reproduction, rendering respiration difficult. Tracheotomy and evislon. Again rapid recurrence. Thyrotomy, evislon, and cauterization with chromic acid. The growths still continued to recur. Death from intercurrent pneumonia. The later portions removed were composed of young embryonic tissue strongly resembling sarcoma.
8	Feb. 14, 1867.	M.	38	Grocer.	Both vocal cords and posterior surface of epiglottis.	Evislon with Fauvel's forceps and cauterization with perchloride of iron.	Ch. Fauvel.	<i>Ibid.</i> , p. 435.	3 years.	Cauterization with nitrate of silver and acid nitrate of mercury. Evislon with forceps. A small portion of the growth still remained. Five years after this there was another marked recurrence, and evislon was again practiced. Patient still under treatment.

No. of case.	Date.	Sex.	Age.	Occupation.	Situation and extent.	Treatment.	Operator.	Reference.	Time of recurrence.	Subsequent treatment; final result; remarks.
9	July 8, 1867.	F.	31	Whole lining membrane of larynx.	Evulsion with tube forceps.	Morell Mackenzie.	<i>Growth in the Larynx</i> , p. 215. Berlin kin. Wochenblatt, 1869, No. 4.	June, 1870 (3 years). Within a short time, cure.	Second series of operations with tube forceps, and recovery of voice.
10	Sept., 1867.	M.	16	Both vocal cords.	Evulsion with wire loop and application of chromic acid.	Toboid.		Within a short time, cure.	Two or three recurrences; ultimate cure.
11	Feb. 4, 1868.	M.	42	Engineer.	Free borders of both vocal cords; of the size of a small bean.	Evulsion with Fauvel's forceps; pedicle still remained.	Ch. Fauvel.	<i>Maladies du larynx</i> , p. 427.	Within 2 months.	Evulsion and cauterization with perchloride of iron; permanent cure.
12	Feb. 8, 1868.	F.	31	Right vocal cord.	Evulsion with tube and common laryngeal forceps.	Morell Mackenzie.	<i>Growth in the Larynx</i> , p. 217; <i>Med. Times and Gazette</i> , June 18, 1868.	Within a short time.	Fresh growth in consequence of not all having been removed on the first occasion; complete recovery ultimately.
13	May 4, 1868.	F.	66	Left ventricular band.	Evulsion of a portion with common laryngeal forceps; subsequently tracheotomy and thyrectomy.	Morell Mackenzie.	<i>Growth in the Larynx</i> , p. 219.	2½ years.	Cure.
14	July 3, 1868.	M.	8	Wine merchant's son.	Right vocal cord.	Evulsion with tube forceps and destruction with caustic solutions.	Morell Mackenzie.	<i>Ibid.</i> , p. 219.	Fresh growth 2 years later on posterior wall and on left ventricular band.	Repetition of treatment and recovery of good voice.
15	Sept. 3, 1868.	M.	61	Upholsterer.	Free borders of both vocal cords and in the angle of the thyroid cartilage.	Evulsion with Fauvel's forceps.	Ch. Fauvel.	<i>Maladies du larynx</i> , p. 465.	Within 1 year.	Evulsion with forceps, repeated at intervals during two months; patient then lost sight of.
16	Nov., 1868.	M.	15	Page.	Left vocal cord.	Evulsion with tube forceps.	Morell Mackenzie.	<i>Growth in the Larynx</i> , p. 219.	10 months.	Second series of operations; cure.
17	June 3, 1870.	F.	26	Large growth upon left side of larynx, and small growth on right vocal cord.	Evulsion with Cuzco's forceps; remains of growth cauterized with carbolic acid.	J. Solis-Cohen.	<i>Diseases of the Throat and Nasal Passages</i> , 3d ed., p. 558.	7 years.	Evulsion and cauterization with nitrate of silver; cure.
18	Aug. 12, 1872.	M.	41	Cashier.	On both vocal cords.	Evulsion with long forceps; growth on left cord not completely removed.	Ch. Fauvel.	<i>Maladies du larynx</i> , p. 549.	Within 4 months.	Evulsion. Nitrate-of-silver solution applied to pedicle; cure.
19	1876.	M.	28	Teamster.	George M. Lefferts.	<i>Med. Record</i> , 1876; <i>Journal of Laryngology</i> , July, 1892, p. 285.	10 years.	For several years after the recurrence the patient had more or less difficulty, and underwent various treatments. In January, 1892, he came under the care of Dr. J. Solis-Cohen. The growth had then penetrated the larynx exteriorly, in a mass larger than an almond. On account of urgent dyspnea, tracheotomy was performed. Finding it impossible to remove the tumor by intralaryngeal procedures, Dr. Solis-Cohen excised the external growth, and then split the larynx and removed every portion of the internal growth. Recurrence took place at the end of four weeks, and the tumor grew very rapidly, protruding again through the thyroid cartilages. On April 1st excision of the larynx was performed, and the patient made an uninterrupted recovery. The growth was pronounced to be a cylindrical epithelioma. Dr. Solis-Cohen expresses the opinion that there was no conversion of a papilloma into a malignant growth, the latter simply becoming developed on the site of the benign growth.
20	Oct. 25, 1880.	F.	28	Anterior angle of vocal cords.	Evulsion with Mackenzie's forceps.	F. H. Hooper.	<i>Archives of Laryngology</i> , vol. iii, p. 855.	Within 1 year.	Growth removed a second time in same way, October 10, 1881.
21	Dec. 2, 1880.	M.	28	Nearly the whole of the right vocal cord, and extending into the right ventricle; small excrescences also on left vocal cord, almost the middle.	Evulsion with Schröter's tube forceps.	F. H. Hooper.	<i>Ibid.</i> , p. 336.	Began to recur at once, spreading and involving the ventricular bands and ary-epiglottic folds.	Repeated operations up to November 1, 1881, when the growth appeared to be arrested. Portions of it still remain, but they give rise to no symptoms.
22	1882.	M.	60	Farmer.	On left ventricular band, covering entire left side of larynx and partially the lower part of right side.	Evulsion.	B. Tauber.	<i>Ibid.</i> , p. 362.	Within 1 year.	Eighteen months after first operation a large growth was found entirely covering the larynx. Tracheotomy, seven eighths of the tumor removed. It subsequently recurred in a malignant form, and in six months terminated fatally. Diagnosis of cancer confirmed by the microscope.
23	Nov. 20, 1883.	M.	35	One large neoplasm at anterior insertion of vocal cords, and another beneath the left cord at its posterior portion.	Snare and Voltolini's sponge.	Lennox Browne.	<i>The Throat and Nose and their Diseases</i> , 3d ed., p. 460.	2½ years.	A small fragment had been left of the former growth, as the patient had to go away. The tumor moved at one sitting under the snare, and the voice again restored.
24	July 11, 1885.	M.	11	Large growth hanging down the glottis from its anterior portion, attached to both vocal cords; another small sessile neoplasm growing from edge of left cord, about its center.	Snare and Voltolini's sponge.	Lennox Browne.	<i>Ibid.</i> , p. 461.	Within 8 months.	The same treatment repeated. Recovery at the end of three months; another recurrence six months later. The treatment was renewed, and at the time of writing (five months after it was resumed) the larynx was clear with the exception of very slight thickening of the right vocal cord. Mr. Browne states that the frequent recurrence and the difficulty of intralaryngeal treatment were so discouraging that he was several times tempted to perform thyrectomy.
25	1881.	F.	Bottom of laryngeal vestibule; of the size of a walnut.	Evulsion; cautery; Voltolini method.	Ariza.	<i>Revista de Med. y Cirug. Práctica</i> , Aug. 7, 1877.	Within a short time.	Neoplasm reproduced in the form of granulations, which grew on all sides. Applications of chloroform-zinc solutions. Cure after four months of treatment.

No. of case.	Date.	Sex.	Age.	Occupation.	Situation and extent.	Treatment.	Operator.	Reference.	Time of recurrence.	Subsequent treatment; final result; remarks.
26	June 11, 1886.	M.	5	Left vocal cord and ventricular band at inter-arytenoid space.	Evisulation with forceps and cauterization with chromic acid.	Joseph H. White.	<i>Journal of Amer. Med. Association</i> , Oct. 22, 1892, p. 478.	4 months.	When the growth recurred it extended to the right side and to the epiglottis. Removal in same way. A second recurrence within one month. Again removed. Within two months the larynx refilled with a cauliflower excrescence. Removal <i>per vias naturales</i> was followed by relief, but as the growth was not entirely destroyed, an attack of suffocation twelve days afterward (which nearly proved fatal) necessitated tracheotomy. Any subsequent attempt to remove the growth resulted in increasing the neoplasm. When all operative interference ceased it began to disappear spontaneously, and the case is now perfectly well. The tube has been worn for five years.
27	Dec., 1887.	M.	10	About two thirds of free edge and lower surface of left vocal cord and the anterior commissure occupied by a large number of small neoplasms, in a cauliflower fashion.	Thyreotomy; the growths removed partly with scissors, partly with a sharp spoon, after which Paquin's cautery was applied to the raw surfaces.	S. S. Eliasberg.	<i>Mémoires de l'Académie de Médecine</i> , 1891, No. 1, p. 46; <i>Journal of Laryngology</i> , June, 1891, p. 245.	Within 2 months.	Thyreotomy again performed by Professor Kosinski, of Warsaw. The neoplasms and the left vocal cord removed. In two months an alarming attack of suffocation, necessitating tracheotomy. In about a month the whole organ became literally blocked up with the tumors; but two months later they began to dwindle away, and in three months more the larynx was perfectly clear. No further relapse.
28	June 17, 1888.	M.	24	Base of epiglottis.	Intubation; cauterization with chromic acid, applied to anterior portion of tube and left in position for a few days; another application then made in the same way.	F. C. Waxham.	<i>Journal of Amer. Med. Association</i> , Oct. 22, 1892, p. 477.	4½ months.	During the absence of Dr. Waxham in Europe, tracheotomy was performed, and when he returned the larynx was firmly sealed by adhesions. Laryngotomy was performed, the adhesions broken up, and the remnants of the papilloma removed. The tracheotomy tube was allowed to remain, and an intubation tube was also used. There was a constant tendency to the return of the growth above the latter, which was as frequently removed by means of the curette. At the end of two years the tracheotomy tube was dispensed with. For two years the patient had worn an intubation tube alone, and he now presented every appearance of health.
29	July 18, 1889.	F.	12	Upper surface of right vocal cord, near the anterior commissure. It extended upward into the vestibule, was oblong in shape, and had an attachment about three eighths by one fourth inch.	Mackenzie's cutting forceps; insufflation of salicylic acid diluted with powdered acacia; tracheotomy, followed by thyreotomy. The growths removed piecemeal by scissors and forceps, and the site curetted with a sharp curette.	F. C. Rayner.	<i>Ibid.</i> , April 30, 1892.	3 months.	Intubation was resorted to on account of dyspnea. Phthisis was detected in the lungs, and seven months after the thyreotomy the child died in suffocative attack before assistance could be obtained. (The intubation tube had been withdrawn.) An autopsy was not permitted, but the author believes that a deposit of tubercle was probably the cause of the laryngeal obstruction at this time, rather than a true recurrence of the papilloma.
30	1890.	M.	12	Larynx filled with papillomata.	Evisulation; later, thyreotomy and destruction of the neoplasms by the sharp spoon and Paquin's cautery.	B. Fraenkel.	<i>Deutsche med. Woch.</i> , 1891, No. 15.	Within 1 year.	Patient still under treatment.
31	Sept. 13, 1890.	F.	6½	Upper surface of left vocal cord and anterior and inner surface of right arytenoid cartilage; of the size of a flattened split pea.	Evisulation with forceps; curette; cauterization with chromic acid.	McDonagh.	<i>Journal of Laryngology</i> , January, 1891, p. 21.	Immediately.	Patient was afterward sent to Mr. Lennox Browne, who removed the neoplasms by evulsion. As the voice soon grew husky again, he removed the tonsils, and also a large number of adenoid vegetations which were found behind the soft palate.
32	Nov., 1890.	F.	10½	Both vocal cords, the anterior surface of the arytenoids, the ventricular bands, and the inter-arytenoid commissure.	Evisulation with Mackenzie's forceps.	J. M. Rees.	<i>Ibid.</i> , July, 1891, p. 291.	Within a short time.	Operation repeated several times, and all kinds of local medication (iactic acid, iron, zinc, etc.), without result. Patient still under treatment.
33	1891.	..	5	Anterior part of larynx.	Tracheotomy; repeated extirpation of the growths.	Peralt.	<i>Annales des maladies de l'oreille, etc.</i> , March, 1892, p. 215.	Within a short time.	Frequent recurrences during eighteen months, but continued amelioration.
34	1891.	..	6	Anterior part of larynx.	Curette.	Peralt.	<i>Ibid.</i>	Within a short time.	Frequent recurrences; but treatment finally resulted in a cure.

Bismuth as a Local Application in Burns.—"The treatment of extensive burns by bismuth, which is employed by Dr. Bardleben in the Friedrichshain Hospital, Berlin, is stated by Dr. Spigearni, of Moscow, to have succeeded admirably in the case of a man who was accidentally burned in a Russian bath by means of a jet of superheated steam. The burn covered the face and the whole surface of the body, with the exception of the feet, the legs, and the lower third of the thighs. When Dr. Spigearni saw him he had been for six days under the care of another surgeon, who had applied iodoform. This was com-

pletely caked by the purulent and serous discharges from the blisters, and the temperature was nearly 102° F. After cleansing the surface thoroughly by means of absorbent cotton wool and boracic lotion it was well powdered over with subnitrate of bismuth enveloped in an absorbent cotton-wool dressing, the latter being omitted from the face, and quinine and stimulants were ordered. A marked improvement soon began to show itself; the dressing was changed three times in the course of the three weeks during which the man remained under treatment, when he was completely cured."—*Lancet*.

CLINICAL REPORTS.

A. Treatment of Seasickness by Atropine and Strychnine.

CASE I.—Madame C., Argentine, aged twenty-nine years. She was the first person upon whom this method was employed. She embarked at Montevideo on April 28, 1886, for Havre.

April 29th.—The patient has been sick abed since the departure of yesterday. She has continual nausea and frequent mucous vomiting. Tongue moist, pale-rose, and free from any coating. Intense frontal cephalalgia; great prostration. Pulse, 80, feeble.

At 7.40 in the morning injection (hypodermic) of one cubic centimetre of the solution of atropine and strychnine. At 7.50, pulse, 75. At 8.10, pulse, 120, still feeble. Vomiting has ceased. At 9.25, pulse, 114. Second injection of one cubic centimetre. At 11.15, pulse 114. Considerable amelioration. There is no more headache or nausea; she is inclined to get up. The patient feels well; she has slept since the first injection.

2 P. M.—She is no longer sick at all and remains on deck.

4 P. M.—She is still doing well, although lying down since a moment ago. She suffers from nothing whatever. Pulse, 78, stronger than this morning.

April 30th.—She passed a good night. A little nausea this morning. At 9.30, pulse, 90, of medium force. Injection of one cubic centimetre of the solution.

May 1st.—She is doing perfectly well. Has not even had nausea or headache since yesterday morning.

CASE II.—Madame G., aged twenty-eight years. Same voyage. A very stout lady.

April 29th.—Has been sick since the beginning of the voyage—i. e., since last evening at 10. Tongue clean, complete anorexia, mucous vomiting, constipation since three days ago, frontal headache, great prostration; is in recumbent position.

At 9 A. M., pulse, 75, feeble. Hypodermic injection of one cubic centimetre of the solution of the sulphates.

11.30.—Pulse, 105, stronger. Has much less cephalalgia. Has slept since the injection. *She wishes her two little girls to have the treatment, as they have both been sick all night.*

10 P. M.—She feels no more nausea, though there is some heaviness of the head.

April 30th.—Passed an excellent night, but on arising this morning she felt nausea and weakness. At 7.30, pulse, 75, feeble. Injection of one cubic centimetre. At 10.30, feels no more nausea at all; headache better; has slept since the injection. *She has eaten with appetite and has retained the food.* After eating she took her work (embroidering), being no longer sick, though the boat still rolls a great deal.

10.30 P. M.—Had a light dinner at 7. Felt a little sick, but no vomiting. The seat of the injections hurt her a little.

Madame G., who has made several long voyages on the ocean, declares that during none of them has she been so little sick as on this one.

CASE III.—Madame G's. children, little girls, one aged five years, the other two years and a half, have also been sick all night and this morning. They had vomiting, pallor, coldness of the extremities, and prostration.

They were treated, in accordance with the repeated request of their mother, in the same manner that she was. The youngest received by injection only one sixth of a cubic centimetre of the solution—that is, 0.00008 of atropine and 0.00016 of strychnine. The elder received somewhat more. The injections were given at ten o'clock in the morning.

At 11.30 A. M. they had not vomited again and were asleep. Two hours after the injection they presented a generalized redness of the skin very pronounced, also slight mydriasis.

2 P. M.—At this hour the children have been for some time on the deck, playing in a lively manner and perfectly cured of their seasickness.

CASE IV.—Madame V., aged twenty-three years, on the same voyage.

April 29th.—She began to be sick about 1 P. M. At three, pulse, 66, feeble; tongue rosy and moist; continual nausea; constipation; prostration, heaviness of the head, face very pale, extremities cold, pupils atresic. Hypodermic injection of one cubic centimetre of the solution.

6 P. M.—Pulse, 84, of medium tension. She has dined and finds herself *quite cured*. The face is rosy; no sensation of heaviness of the head. Pupils normal.

CASE V.—Mrs. W., aged thirty years, same voyage.

April 29th.—Sick ever since early morning. The tongue is normal. Abundant and frequent mucous vomiting. Constipation, frontal cephalalgia, moderate prostration, recumbent position. Pulse, 65, feeble.

8.35 A. M.—Hypodermic injection of one cubic centimetre of the solution. *At nine o'clock she gets up* and feels no more nausea; she feels well; the face is no longer pale as before; there is no more headache or prostration.

6 P. M.—The amelioration continues. She has dined well and shows no symptoms of seasickness.

10 P. M.—Some nausea on retiring for the night. Pulse, 72. No other symptoms. Injection of one cubic centimetre.

30th.—She passed a very good night and feels in excellent health on arising this morning.

11.35 A. M.—Vomiting since breakfast at ten. Some frontal headache. Pulse, 72. Injection of three fourths of a cubic centimetre of the solution of the two alkaloids.

1.30 P. M.—Pulse, 100, rather strong. The patient says that since half an hour ago she does not see well; there seems to be a veil before the eyes. No iridescence upon objects seen, no mydriasis, no other inconvenience from the injection (amblyopia).

7 P. M.—She has vomited a little once or twice since dinner at five o'clock. Dryness of the mouth.

The patient, who has made other voyages, affirms that she has never been so well during their first days as she is during this.

May 1st, 7.45 A. M.—Examination shows that the heart is normal. The corneal, patellar, and plantar reflexes are normal. The patient is still lying in bed. Pulse, 81, tension and rhythm normal. Has slight frontal headache. Face slightly congested, pupils normal, extremities warm; constipation since three days. By precaution (because she has no nausea or vomiting for the moment), a pill is given her which contains quinine sulphate, strychnine sulphate, belladonna extract, and alcoholic extract of rhubarb. This pill was administered three quarters of an hour before she arose. She vomited but once, and that was two hours after arising.

11 A. M.—Less headache, no more visual trouble. She reports herself much better. Pulse, 75, of medium strength.

She was not seasick any more during the voyage, which lasted twenty-four days.

CASE VI.—Master W., aged eight years, son.

April 29th.—Began to be sick after breakfast at ten.

3 P. M.—Nausea; tongue slightly coated; abundant and troublesome salivation; no headache; notable prostration; position half reclining and motionless; very marked pallor of face, coldness of extremities, pupillary atresia; pulse, 72, feeble. Injection of half a cubic centimetre of the solution.

7 P. M.—Pulse, 78, stronger, but somewhat irregular. He has not been sick at all since receiving that single small injection. He is gay and smiling on going to bed. The pallor of the face is replaced by a rosy tint. There is no longer any abnormal salivation.

May 6th.—Was not seasick any more during the voyage.

CASE VII.—Master Augustus W., aged six years, son.

April 29th, 5 P. M.—Has vomited several times; is dull and listless; pallor of face, coldness of extremities, pupils normal; pulse, 84. Injection of one fourth of a cubic centimetre.

7 P. M.—Pulse, 108, of medium strength. Remarkable amelioration in general condition. Sleeps quietly without having had any more vomiting. Cheeks rosy, hands warm.

30th.—Is no longer sick at all. Plays gayly, as does also his brother.

May 6th.—Remains thoroughly well.

CASE VIII.—Mr. B., aged thirty-eight years, same voyage.

April 29th.—Has been sick all day and stayed abed. *He has not ceased to vomit almost continuously.*

6 P. M.—The mucous vomiting continues very profusely; complete anorexia; constipation; tongue slightly foul; no frontal headache; very great degree of prostration. Pulse, 57, of medium tension. Injection of one cubic centimetre.

9 P. M.—He feels *no more nausea at all*. He has slept soundly since the injection. The face is no longer pale.

30th.—Passed an excellent night. Slept soundly without any nausea.

6.30 P. M.—He received no injection during the whole day and was *seasick all the time*. This evening he has vomiting, pallor of the face, very decided coldness of the hands, cephalalgia, prostration, and weakness. The patellar and corneal reflexes are normal. Heart healthy. Has had a semisolid stool. Pulse, 45, feeble. Injection of one cubic centimetre.

May 1st, 8 A. M.—The night was passed very comfortably. This morning the extremities are warm, the face rosy, and there is less prostration. Pulse, 48.

CASE IX.—Mlle. S. V., aged nineteen years.

April 29th, 12 M.—Alimentary and mucous vomiting; tongue clean; occupies a sitting position; no headache. Pulse, 100, feeble. Injection of one cubic centimetre.

2 P. M.—Pulse, 114, stronger. No more vomiting, and not even any nausea.

6 P. M.—Pulse, 51, medium tension. Commenced to vomit again after dinner at five.

7 P. M.—Pulse, 57, feeble. Injection of one cubic centimetre.

May 5th.—The patient has shown *no more symptoms of seasickness* since the last injection.

CASE X.—Mlle. Catherine X., aged thirty-six years. (This case is interesting on account of the failure of the treatment owing to a cardiac lesion.)

April 29th.—Patient is sick since early morning. At 9.30 A. M., injection of one cubic centimetre.

12 M.—Has vomited several times since the injection. Pulse, 116, feeble. Second injection of one cubic centimetre.

3.45 P. M.—No improvement; vomiting has continued since second injection; tongue slightly coated; some nausea, dizziness, but no headache; pupils normal; pallor of face and coldness of extremities. Pulse, 72, feeble. Third injection of one cubic centimetre.

6 P. M.—No amelioration.

30th.—Still some nausea. Toward evening she feels better.

May 2d.—Examination of the heart reveals *well-characterized mitral regurgitation*.

B. Treatment of Naupathia by Caffeine.

CASE XI.—Madame L., aged twenty-one years, sailed from Bordeaux for New Orleans on August 14, 1886, on the steamship *Marseille*.

August 17th.—Patient has been seasick ever since the departure three days ago. She has not left her bed and has eaten nothing.

9.30 A. M.—Very great prostration; severe frontal cephalalgia; gastralgia. Pulse, 114, small, feeble; rectal temperature, 37.6° C. (99.7° F.).

Treatment.—Subcutaneous injection of three quarters of a cubic centimetre of the solution of caffeine described before—*i. e.*, three tenths of a gramme of caffeine and about a fifth of a gramme of sodium salicylate.

10 A. M.—Pulse, 78, fuller, stronger. She feels better.

11.40 A. M.—Pulse, 75, stronger. Feels herself still better. No more headache or gastralgia. She still remains abed, and is not hungry. Rectal temperature, 37.3°.

4.30 P. M.—Pulse, 90, fairly strong. *She feels perfectly comfortable*, though still abed. Later she went to dinner for the first time since embarking.

20th.—She has been well since last note.

CASE XII.—Mlle. M. P., aged eighteen years. Same voyage as last case.

August 17th.—She has also been seasick ever since leaving Bordeaux three days ago. She keeps her bed and has eaten very little. No evacuation of the bowels since embarking.

10.10 A. M.—Pulse, 84, feeble; rectal temperature, 37.6° C. Cephalalgia; gastralgia. Injection of three quarters of a centimetre (three tenths of a gramme) of the solution of caffeine.

12 M.—Pulse, 72, still feeble and intermittent, as it was also at first visit at 10.10 A. M. Rectal temperature, 37.7°. No improvement.

4.30 P. M.—Pulse, 96, much stronger. *Notable amelioration.* She talks and laughs with the other passengers, and remains sitting up in bed.

20th.—She remains cured.

CASE XIII.—This case shows the remarkable effect of this method of treatment. Paula X., aged eight years, a tawny-colored native of the Cape Verde Islands, was one of our passengers from those islands to Buenos Ayres. She began to be sick in the dory while being rowed to the steamship, and when on board she was violently sick every day, so that she could keep absolutely no aliments on her stomach, neither solids nor fluids. She was compelled to lie down almost the whole time vomiting at frequent intervals. This state of affairs continued during six days in succession without her receiving any treatment, and by that time she had become so feeble and emaciated that the captain, to whom she was given in charge, became alarmed about her and asked us to apply our method of treatment. At ten o'clock on the sixth day we gave her a hypodermic injection of one third of a cubic centimetre of the solution of atropine and strychnine—*i. e.*, about 0.0003 of a gramme (or about one two hundredth of a grain) of each of these alkaloids. *Three quarters of an hour afterward she sat up at a table and ate and drank with great appetite.* She kept everything upon her stomach without nausea, and from that moment she felt no longer seasick, but, on the contrary, she ate well and soon began to play. The state of the sea had no influence in her recovery, for the weather had been uniformly fair all the time. This is one of the most striking examples of cure we have seen.

We could produce many more clinical reports of trials of this method of treatment, but we judge it unnecessary. It is to be remarked that the above reports cite the disagreeable effects and the failures as well as the advantages and successes of the method. Any physician, on employing the same mode of treatment, would, no doubt, have the same degree of success as we have had.

Conclusions.—1. The principal symptoms of naupathia result from the lowering of the patient's arterial blood pressure. This is a condition *sine qua non* of their development.

2. Seasickness in a person otherwise healthy and not too aged is *promptly curable* in the vast majority of cases.

3. Even in aged persons, or in persons having certain affections of the circulatory apparatus, there is often amelioration of the general condition by the employment of the new method of treatment.

4. The treatment consists in the hypodermic injection of from half a milligramme to a milligramme of atropine sulphate, associated with a milligramme of strychnine sulphate (or nitrate), dissolved in a cubic centimetre of distilled mint water.

5. The administration of these eminently toxic substances demands a great degree of attention, prudence, and supervision on the part of the physician, who alone should be the judge of the opportunity of their administration and of their dose in each individual case. Given at proper times and in suitable doses, however, no harm whatever will follow their administration.

6. The sympathetic nervous system plays a preponderating rôle in the causation of naupathia.

7. Naupathia, or seasickness—an affection without known anatomical lesions, and of which the predominant symptoms have their origin in the nervous system, and especially in the sympathetic or ganglionic nervous system—ought to be regarded as a *neurosis of the sympathetic*.

8. This neurosis may recur during the course of a long voyage, but each attack is almost always amenable to the same treatment.

EXCISION OF SPINA BIFIDA,

WITH RECOVERY.

By CLINTON B. HERRICK, M.D.,

ASSISTANT ATTENDING SURGEON, TROY HOSPITAL;
ATTENDING PHYSICIAN AND SURGEON, COUNTY HOSPITAL, TROY, N. Y.

SPINA BIFIDA are not infrequently met with, and when they are it is as often puzzling to the surgeon as to how to handle them. The diagnosis is comparatively easy, but it is not always possible to determine the exact condition of the tumor. Whether the foramen is small or large, whether there is much or any of the cord issuing from the fissure, can only be conjectured.

While in some cases the walls of the sac are so thin as to allow its transparency to assist the observer, in others the skin and sac coverings are thick and boggy, obscuring every sense of determination. Thus it is that the many methods advised and few successes reported embarrass the surgeon in his efforts to relieve his little patient. All au-

thorities seem to agree that an incision into the sac, with a consequent draining off of the cerebro-spinal fluid, is followed by immediate dire results, such as convulsions, shock, and death.

Having observed a case where the sac had ruptured at or before birth, followed by a continuous discharge of fluid without any apparent effect on the mental or physical condition of the child, I formed the idea that evil effects from an incision must be accidental only. Therefore, when confronted by the case to be related, I decided at once to advise complete excision and meet what came:

The child was six weeks old. At his birth a small "lump" was noticed in the lower lumbar region which gradually increased in size. Otherwise the babe was healthy and perfectly formed. No history of specific trouble in the parentage was found, and none others of several children were misformed. When I saw the child in June, 1893, I found an ovoid tumor in the lumbar region about four inches in its longest diameter, or of about the size of the largest orange. It was cystic to the

touch, pinkish in hue, with radiating vessels on the surface. The normal skin extended on both sides up on the tumor to the distance of about an inch and a half, in an irregular line, from where a membranous-looking covering continued over to meet the skin line of the other side. The base constituted a broad pedicle. The size of the foramen could not be determined. Preliminary to operation an aspirator needle was introduced and about three ounces of fluid removed without any unpleasant symptom. On the following day the tumor had resumed its former size.

The Vienna mixture was administered, and the cyst again punctured as before. When it was nearly empty, an incision was made the entire length in the median line, exposing the inside of the cyst. This surface was pinkish and smooth, and leading from a foramen, the size of the end of the little finger, were very large nerve filaments, which coursed on the upper surface of the sac, ending rather bluntly. In addition to the large ones, were one or two thread-like nerves issuing from the foramen. Hemorrhage was considerable. The filaments were dissected from the wall with but little difficulty, and restored into the canal by a probe through the foramen.

Fluid leaked continually. The superabundant sac was purposely cut away down to the level of the skin so as to necessitate some traction on the latter to enforce pressure. Sutures of silkworm gut were placed very close to bring the edges of the wound in tight apposition. At the close of the operation there was no leakage of fluid. Aristol and collodion gauze were quickly applied and firmly bandaged. As all went well, the dressings were not changed for four days. Not an unpleasant

symptom arose during the entire time. The stitches were removed on the seventh day, showing all firmly united, and the child was waxing strong. At the present writing there is no sign of return of the tumor.

A CLINICAL PAPER ON SOME CASES WITH VARIOUS INTERESTING FEATURES.*

1. COMPLETE INVERSION OF THE UTERUS.
2. FRACTURE OF THE RADIUS IMMEDIATELY BELOW THE BICIPITAL TUBEROSITY.
3. INTESTINO-PERITONEAL SEPTICÆMIA.
4. VENTRAL HERNIA.

By IRVING S. HAYNES, M. D.,

DEMONSTRATOR OF ANATOMY,
MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK;
ASSISTANT SURGEON, ORTHOPEDIC HOSPITAL, ETC.

CASE I. Complete Inversion of the Uterus.—Mrs. A. S., aged twenty-one years; first child on November 1, 1888; lived one day; mother made a speedy recovery.

Second child on October 26, 1889; born at 8.15 P. M.; delivered by a midwife, who left about 9 P. M. At 9.30 after-pains began, and became more severe from hour to hour until, about 2 A. M., they called for me (October 27th, Sunday).

On reaching the house, found a strong, healthy young German woman in great pain. Paroxysms every half minute, during which she cried out loudly, rolled from one side of the bed to the other, and bore down very hard. Morphine, a quarter of a grain hypodermically.

Examination.—On separating vulva and removing blood clots, exposed a large, round tumor that forcibly contracted and hardened with every pain.

Tumor as large as a large coconut, reaching just to vulva. Fingers passed all around it below; above it was attached by a broad pedicle to upper part of the vagina.

Abdominal palpation showed no uterus in pelvic region.

During the pains she bore down so hard that it seemed as if she would drive the entire contents of the abdomen through the vagina.

Diagnosis.—Complete inversion of uterus.

Treatment.—Midwife had returned after being sent for. She said she understood giving ether, so I had her start it while I administered a large, hot bichloride douche. The woman did not succeed with the ether, and I had to take the cone. While administering the ether with the left hand, the inversion was reduced by the other in the following manner:

The right hand was well covered with carbolized vaseline, and pressure made upon the lowest and most prominent part of the uterus with the ends of the fingers bunched together. Had to relinquish this manoeuvre, as on very slight pressure the uterine tissue gave way, making a slight tear.

Then the last two sets of phalanges were flexed to a right angle and pressure made with their dorsal surface. Gradually the uterus was indented, and in about twenty minutes fully returned to its natural position. Ether stopped.

A hot intra-uterine bichloride douche (1 to 4,000) given.

Uterus semi-relaxed, reaching as high as the umbilicus.

It was constantly, but gently, manipulated for half an hour, and contractions resulted about every three minutes, but they were so feeble that hæmorrhage was feared any moment, but fortunately did not occur. At the end of this time the uterus became a little firmer, and, when it did contract, produced such

severe pain that morphine was again given to full physiological effect.

About 4 A. M. the uterus became somewhat more relaxed. A hot douche was given with good results for a little while. As it showed symptoms of again becoming relaxed, half a drachm of ergot was administered every half hour.

By 6 A. M. the uterus was in fair shape, only partially contracted, however, and during contractions could be felt as high as the umbilicus; between the contractions it felt like a boggy mass filling the pelvis.

A binder was applied, and ten grains of chloral and fifteen of bromide of sodium were to be given every hour if necessary.

At 10 A. M. the temperature and pulse were normal; the patient was fairly comfortable; did not complain of pain, but left iliac fossa exquisitely tender on touch.

Convalescence was uneventful and steady. The tenderness in iliac fossa left after a saline laxative had been given.

The temperature was highest, 100° F., on the third day, and became normal as soon as needleless feather beds (used for blankets) were removed and a very hot room cooled down.

By the eighth day I found her up and nursing the baby. I ordered her to keep quiet. By the eighteenth day she was doing her own work and said she was as well as ever.

In looking for the ætiology of the case, I asked the old German midwife at the first breathing spell after the reduction of the inversion if she had allowed the "after-birth" to come away by itself. "Why, no," said she. "I helped it along mit der shtring."

If this procedure did not produce the entire inversion, it undoubtedly started it by bringing down a part of the uterus into the grasp of the cervix.

The severity of the pains and the great straining and bearing down while the uterus was inverted were entirely unlike labor pains or any bowel tenesmus, and are peculiar, I think, to this affection alone.

The friability of the uterine tissues impressed me after making a hole in them by the blunt ends of my fingers. However, on turning a still broader surface to the uterus in the shape of the back of my fingers, the uterus was gradually reduced without any other rents being made.

From this experience, I believe it would be dangerous to use any of the instruments advised for this purpose, for I am sure that if the utmost care was not used the instrument could be pushed right through the uterus.

If I had had an instrument in place of my fingers I should never have been aware of the laceration that resulted. I believe the hand is superior to any and all instruments for cases like this.

The prolonged flaccid condition of the uterus after reduction was no doubt due to muscular paralysis following its severe contractions in an abnormal position.

The freedom from hæmorrhage and the scanty discharge afterward were noticeable.

There was no fever whatever due to the accident, but 1.4° due to a hot room and excessive covering.

Occurrence.—Playfair gives the ratio of acute inversion to births as 1 to 190,000.

The symptoms, aside from the tumor, "profound nervous shock, severe abdominal pain and cramp, and bearing down." "Hæmorrhage is a frequent accompaniment," he

* Read before the Society of the Alumni of Bellevue Hospital, October 4, 1893. For the discussion see page 643.

says. In this case there was no shock to speak of, and no hæmorrhage before, during, or after the inversion.

Under reduction, he says, "the inverted portion of the uterus should be grasped in the hollow of the hand and pushed gently and firmly upward into its natural position."

The plan I used is said by McClintock to increase the bulk of the mass and so increase the difficulty of reduction.

In regard to the former opinions, I would ask you to get a large cocoanut—one five inches in diameter—and see how much pressure you can exert upon its sides by grasping it in the "hollow of the hand"; convert the case into one of inverted uterus and you will agree with me that this mode of reduction, while, perhaps, theoretically practicable, is practically impossible. In regard to the latter opinion, I would say that the reduction is easiest and more rational by denting the projecting fundus and so turning the uterus back that the size of the mass to the state of the cervix does not make much difference within reasonable limits, for with the cervix just having expanded sufficiently for passage of the fetal head, it will again expand under an anæsthetic and allow passage of the returning uterus and the hand of the operator.

Probably if I had had one of the large rubber bags and the accompanying force pump at the time, I should have used it, and possibly with complete success. But on the whole I think the hand is preferable, for you then know every change in the surroundings and do not have to go ahead in the dark.

The intra-uterine douches are very beneficial, as all agree, in promoting subsequent contraction. They acted well in this case, but their effect was not of long duration.

CASE II. Fracture of the Radius immediately below the Bicipital Tuberosity.—Harry R., aged four years, July 8, 1891, fell from a bicycle on to right arm. Just how, not known.

Examination, a few minutes after the accident.

Voluntary movements of forearm and elbow lost. Forearm between pronation and supination at right angles to arm. If it is extended, a swelling appears about an inch below the bend of the elbow over the radius. At this point there is abnormal mobility and greatest pain, but no crepitus elicited.

Diagnosis.—As above.

Treatment.—Plaster-of-Paris splint applied, with forearm completely supinated and flexed to ninety degrees with arm.

New splint July 15th. Removed August 4th; union perfect.

Pronation and supination only one third and slight stiffness at elbow, which disappeared entirely after three or four weeks without interference, giving perfect movements at elbow and between the radius and ulna.

The authors all agree in stating that the accident is a rare one.

Treves, in his *Applied Anatomy*, states the symptoms: "When the radius is broken between the insertion of the biceps and pronator radii teres, the upper fragment is flexed by the biceps and fully supinated by that muscle and the small supinator. The lower fragment will be pronated by the two pronators and drawn in toward the ulna by means of those muscles."

This case illustrated these theoretical symptoms almost perfectly.

On extension of the forearm the upper fragment was retained in a position of flexion, and no doubt supination; the swelling over the forearm and just below the elbow was due to the projection forward of the upper fragment on extension; it disappeared on flexion. The hand was held in a position midway between pronation and supination.

The position of full supination was well borne—in fact, caused no inconvenience whatever, for the boy made no complaint at any time.

The stiffness in the forearm movements disappeared on allowing the child to use its arm without any interference.

I believe in the teaching of Professor Stimson, that the fear of joint ankylosis—ankylophobia—and the consequent passive motion kept up in season and out, is responsible for many cases of limited or even no motion after such injuries.

I believe in letting them entirely alone for a reasonable time, and let the patient use his limb to suit himself.

I have seen complete ankylosis at the elbow following a dislocation entirely recovered from in eight weeks without any treatment whatever.

CASE III. Intestino-peritoneal Septicæmia.—Mrs. S., aged twenty-six years, February 21, 1892, delivered of a good-sized boy after a labor of about ten hours. At the beginning of the labor the ostium vaginae would barely admit two fingers, which caused considerable pain. The perineum was dense and firm and was stretched intermittently by bearing downward and backward until three, then four fingers, and finally the whole hand was admitted. At the delivery the perineum was only slightly nicked, but I am confident would have been split to the anus but for the intermittent stretching. This procedure was suggested in the *Record or Journal* by a writer. I can not find the article now.

Case progressed perfectly normal without a single bad symptom until the 28th—seven days after the confinement.

On the 28th, at 4 p. m., she had a severe chill. At 7 p. m., temperature, 104° F.; pulse, 150; respiration, 24. Very restless, face flushed, skin hot and dry, felt very badly, was afraid she was going to die.

Carbolic douches had been given morning and evening from the first. The lochia had been natural and without odor for the entire time. The bowels had not moved since the 26th.

Tablespoonful doses of Tarrant's aperient were ordered every hour until the bowels moved. Five grains of sulphate of quinine every four hours.

February 29th, 10 A. M.—Temperature, 104° F.; pulse, 150; respiration, 24. Symptoms not improved. Bowels had not acted freely.

Thinking that perhaps there might be some trouble in the uterus, I gave chloroform and curetted, but it was absolutely free from the least trouble whatever.

Intra-uterine douche of carbolic solution. Salines kept up. During the afternoon the bowels moved three times; 7 p. m., temperature, 103° 4' F.; pulse, 120.

March 1st, A. M.—Temperature normal; bowels moved several times during the night. Feeling all right, but weak. Recovery uninterrupted.

Here is a clear case of self-infection from intestinal bacteria allowed to develop during two days of constipation and probably penetrating to the peritoneal cavity. Relieved by free saline cathartics. I do not think anything else had any bearing upon the treatment, except possibly

the carbolic douches might help to restrain bacterial action; but just as soon as the bowels began to act freely and afford free drainage from the abdominal cavity the symptoms began to mend. I believe that in these cases, even when the septicæmia is due to uterine infection, saline cathartics, plus the intra-uterine treatment, are the most useful means we have to prevent further infection.

CASE IV. *Ventral Hernia*.—Mrs. B., aged about forty-five years. Large-sized woman; mother of large family.

In 1883, after birth of a child, noticed a lump between navel and pubes. This gradually increased in size without causing her any particular discomfort. Was reducible itself on lying down.

In 1885 began to wear a large pan-shaped abdominal truss that did not keep the rupture in place.

In 1887 she had an attack of obstructed bowel. Tumor came down, was painful, and the bowels constipated. The doctor called administered a cathartic, which acted. The attack only lasted two days, but the lump did not go away for two weeks.

The case was uneventful, excepting chronic constipation, until March 24, 1891, when the rupture again came down and could not be reduced. They called for me and I found the usual symptoms of an obstructed hernia. The hernia was larger than usual, she stated; was about six inches in diameter, circular in shape, and most prominent point about two inches above proper level of the abdominal wall; tender to touch; considerable pain. Attack brought on by hard work at lifting furniture, etc., in spring cleaning.

An eighth of a grain of morphine every hour if necessary. Hot poultices. Operation advised but not accepted. Bowels moved satisfactorily on the next day after a high injection and the tumor diminished in size, but a large, doughy mass remained behind.

She finally consented to the operation and was prepared for it with diet and whisky until the 28th, when, with the help of Dr. Bauer, Dr. O'Neil, and Dr. Welch, the operation was undertaken.

All precautions against shock and sepsis taken.

Usual incision. Sac opened at once; consisted only of peritonæum and skin closely blended and much thinned from pressure.

A dark mass of omentum exposed. It was attached by its base to the sac all about the hernial orifice.

Adhesions broken down and omentum examined for contained intestine, but none found. The omentum from the congestion and hyperplasia was nearly half an inch thick and, when spread out, six or eight inches wide along its outer margin, being, of course, fan-shaped. It completely filled the opening of the sac.

It really looked as if a process of degeneration had begun in it, and it was deemed best to remove it. This was accordingly done in the usual manner by several interlocking silk ligatures. Pedicle examined for bleeding points; none being found, it was returned to abdomen. Opening of hernia circular and about an inch in diameter. The sac for a distance of about two inches around the orifice was dissected up and its neck freed from the fibrous ring. Neck of sac tied off by a heavy silk ligature and the rest cut away. The margins of the ring were brought together with heavy buried silk sutures. The redundant portions of skin removed and the edges sutured. Drainage-tube inserted. Heavy dressing applied.

Convalescence progressed favorably with some little fever. On the fifth day superficial sutures and tube were removed. Union firm. The external wound closed up, yet there was some pain about the seat of operation and a degree or two of fever.

About two weeks later a definite point of fluctuation below and to the right of the incision was detected. This abscess was opened and a drachm or two of pus evacuated, in which was one of the deep sutures. This abscess discharged until all the deep sutures were removed. It then closed up and left only a small scar. The sutures were divided and taken out as fast as they appeared; a probe curved at the end was used to nook then into the wound so they could be removed. Patient was up and around the house during this time. After the last suture was removed the sinus closed and she wore a light bandage, which she continued for some months.

There was no return of the rupture until the spring of 1893—about two years—when she said a small lump appeared. Had not been wearing bandage for over a year. She was ordered to resume its use.

September 30, 1893.—Examination: She states rupture comes down, but she can replace it. She can not find the opening, however. When fully distended, rupture as large as a small orange. The rupture was not down at the time of examination. The orifice of the hernia was found, but would not admit any of my fingers. It is situated half way between umbilicus and pubes in median line. On coughing, a small knuckle of gut is forced out, but immediately returned to abdominal cavity on slight pressure.

Another operation advised with pretty sure hopes of cure, but she has all she wants of operations, she says. Bandage advised and a truss later if she can not get along.

If no operation had been done it is possible that the mass of omentum might have become so adherent to the ring as to close it up and produce a cure; yet the dangers of intra-omental hernia would have remained. On the other hand, the omentum might have sloughed, for it was very dark and congested. If the ring had been closed by perfectly aseptic catgut sutures the suppuration would have been omitted. It is probable that one or more of the sutures carried the infection. At any rate, the wound did not close until the last of them was removed. Yet all this time the silk on the pedicles of the omentum and peritonæum gave no trouble, and the cutaneous incision, also sutured with silk, closed without suture abscesses.

The suppuration had nothing to do with the return of the hernia, to my mind, for the reason that the granulation tissue formed on cicatrizing would aid in closing the orifice. If, however, the orifice gaped and the connective tissue alone remained, a weak spot was surely left.

Doing the operation again I would still use silk, but would redouble all antiseptic efforts.

The woman is well to-day and the operation has served to clean out all the omentum and to give us a hernia with a small orifice—a favorable condition for operation, but much more dangerous for the woman.

After the operation there was freedom from a hernia for nearly two years.

131 EAST EIGHTY-SIXTH STREET.

The Royal College of Physicians, of London.—A very close vote occurred in the college on the occasion of the recent election of a new president in place of Sir Andrew Clark, deceased. Dr. J. Russell Reynolds had seventy-five votes, while Dr. Samuel Wilks received seventy-two votes. The former represents the interests of University College; the latter those of Guy's Hospital.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 30, 1893.

THE NEW PHARMACOPEIA.

THE seventh decennial revision of the United States Pharmacopœia, nominally for 1890, has recently been published, and is to be official from January 1, 1894. In size and general appearance it does not differ materially from the Pharmacopœia of 1880, but, if our memory serves, the delay in its appearance has been more considerable. The strict alphabetical arrangement of subjects adopted in the Pharmacopœia of 1880 has been retained, and this fact, it seems to us, goes far toward making the book useful to pharmacists rather than to physicians; but this defect, from our point of view, is mitigated by the fact that a list of preparations into which each individual drug enters is given at the conclusion of the article on that drug. Nevertheless, some confusion may arise in certain instances—for example, the new Pharmacopœia contains no such heading as *aloes*, but it does give *aloe barbadensis*, *aloe purificata*, and *aloe socotrina*, while under the head of *extractum aloes* it says “*aloes*, one hundred grammes,” etc. It is true, however, that the name of the preparation *extractum aloes* is given at the conclusion of the article on *aloe socotrina*, and not in the article on any other form of *aloes*, so that the student who happens to possess the perseverance of an antiquary may ascertain, if he takes the trouble, that when, under the head of *extractum aloes*, “*aloes*” is specified, *socotrine aloes* is meant. The following statement is made in the preface: “A strong effort is at present being made both in Europe and in this country, though not, as yet, by concerted action, to reform the chemical nomenclature, more particularly with the object of making the name of a substance convey, as far as possible, some information as to its nature and constitution, or as to the class to which it belongs. An appeal was made to the committee of revision to join in the movement—in fact, to adopt the newly proposed spellings and terms. Among these propositions were the spellings: bromin, chlorin, fluorin, and iodin, for bromine, chlorine, fluorine, and iodine; bromid, chlorid, iodid, oxid, sulphid, etc., for bromide, chloride, iodide, oxide, sulphide, etc.; aconitin, morphin, quinin, etc., for aconitine, morphine, quinine, etc.—thus abolishing the hitherto prevailing distinction in spelling between alkaloids and so-called neutral principles—sulfur, sulfate, etc., for sulphur, sulphate, etc.; glycerol, benzene, etc., for glycerin, benzol, etc. While some of the members, individually, were willing to approve and adopt at least some of these new spellings in their professional writings, the decision, so far as the Pharmacopœia is concerned, was almost unanimously against their adoption at this time, it being deemed unsafe and unnecessary

to inaugurate such radical changes, not yet generally accepted or followed in practice, in the names of medicines familiar, under their present garb, to so large a proportion of the population.” For this we are thankful; there has of late been shown what we are constrained to consider an undue propensity to change the forms of old and familiar words.

We find that ninety titles have been dismissed from the Pharmacopœia, and that eighty-eight have been added. Those dismissed include all the abstracts, and we think their rejection was justified. The more important of the articles added are acetanilide, convallaria, menthol, naphthaline (called in the Pharmacopœia *naphthalinum*), naphthol (*naphtol*), pancreatin, paraldehyde, pyrogallol, resorcin, strophanthus, terebene, and *Viburnum opulus*.

THE EFFECT OF “CASTRATION” ON WOMEN.

THERE is probably no question in gynecology regarding which more divergent views are entertained than that of the effect of “castration” on women. Dr. William Goodell publishes in the *Medical News* for December 9th an interesting contribution to this question. He agrees with Hegar that the artificial menopause induced by operation is often attended with more serious complications than those that are not rarely observed in the natural change of life. Then, again, mental disturbances, manifested by brooding, by low spirits, by melancholy, and even by insanity, may be traced directly to oophorectomy as a cause. Keith has stated that ten per cent. of his patients that recover from hysterectomy subsequently suffer from melancholia or from other forms of mental disease; and another author declares that in almost all cases the mind becomes more or less affected, and not infrequently melancholia results.

In his earlier teachings Dr. Goodell maintained that oophorectomy after puberty did not completely unsex a woman; her capability of being impregnated was lost, but her sexual feelings remained much the same. In this he agreed with Kæberlé, who held that it caused no marked change in the condition of those that had been operated on; they were women that had abruptly reached the climacteric, but their instincts and affections remained the same, and their sexual organs continued to be excitable. But a riper experience has forced him to the conclusion that in the majority of women that have been “castrated” the sexual impulse soon abates in intensity, much sooner than after the natural menopause, and that in many cases it wholly disappears. This corroborates the report of the special committee appointed to investigate Imlach's cases of “castration” at the Woman's Hospital in Liverpool; they found “a distinct loss of sexual feeling to such an extent as to cause serious domestic unhappiness in not a few instances.”

Otherwise he has found no marked physical or psychical change. The affections remain the same, the breasts do not flatten or wither, obesity does not ensue, neither facial nor corporeal hirsuties follows, and the tone and quality of the voice are unchanged; in other words, there is no tendency toward any characteristics of the male type. If any change takes

place, it has been in the direction of old-maidhood. But the loss of sexual feeling has caused broken engagements, conjugal estrangements, and marital infidelity.

In consequence of this experience, he advises that an effort be made to restore a woman's health by resorting to other than operative procedures. If oophorectomy is the *dernier ressort*, then, he says, never remove a healthy appendage unless the menopause is already established or unless there is good reason for hastening it. The latter may be the case for women with excessive or abnormal sexual appetites consequent upon continuous ovarian or uterine irritability that is the result of some local disease; in such, oophorectomy usually results in the extinction of the appetite. Should the uterine appendages be merely adherent and not intrinsically diseased to any extent, and should there be active menstrual life, we may release the appendages and perhaps remove the more diseased of the two, but not both of them. Even a small fragment of ovarian stroma that is left behind may prevent any menstrual or sexual change whatever occurring in the woman.

This exposition of some of the unfortunate ulterior consequences of "castration," and this plea for greater conservatism in resorting thereto, should receive wide attention in a country where physicians are all too ready to assume that an operation will relieve the symptoms attendant upon ovarian or uterine disease.

MINOR PARAGRAPHS.

THE SICK BAY ON THE MAN-OF-WAR NEW YORK.

WE copy from one of the daily papers a portion of its description of the hospital accommodations on the New York. It has been stated officially and otherwise that this provision was of an inadequate nature, but we had not imagined for a moment that the government of any civilized country could permit a state of things such as this is described to be. The ship should not be allowed to go out of port without this fault having first been remedied.

"The New York man-of-war is getting ready for sea. The vessel will have six hundred men on board when she goes out, and it is believed her destination will be Brazil, where disturbances are quite possible and where diseases lurk in the air. For these six hundred men there are hospital accommodations which will hold just two at a time. If three men are sick enough to go to hospital, two can be taken to the 'sick bay' or hospital, and the other one can be thrown overboard, but in no event can he be taken to the sick bay, because there is only room for two there at a time. This sick bay is at the extreme forward part of the ship with the anchor chains making music through great tubes at the head of the inclosure and with the dynamite room on the immediate right. Back of the sick bay is what is called the surgical 'operating room.' It is a bathroom. They put a board over the bath tub and that is the operating table."

ANOTHER NEW HOSPITAL SAID TO BE NEEDED.

ONE or two of our daily papers call attention to the difficulty and delay that often attend the disposition of persons with acute mania. It is held that there is need for some provisional infirmary where the violent insane may be properly cared for before they are regularly committed to an asylum. It might even be that, in such special provision, some patients

might recover without the odium of a recorded transfer to a lunatic asylum. At present the "cells" of Bellevue meet the requirement in a measure.

THE PRESBYTERIAN HOSPITAL.

THE annual report of this institution shows a large increase of its benefaction to the poor as compared with former years. The average of daily occupied beds has risen from 133 to 155; the number of persons who received treatment in the hospital was only a little short of 5,000, and the ambulance calls were over 1,800. The dispensary shows a large increase of work performed, the total number of patients treated having risen to 10,626. In the hospital proper the total number of days of treatment was 56,500, with an expense account of \$58,063, which is tantamount to a per diem cost of \$1.02 for each patient. A legacy of \$217,000 from the estate of Mrs. Mary Stuart was received during the year.

SOMETHING OF AN ANTICLIMAX.

THE St. Louis *Globe-Democrat* recently published a communication from a physician the purpose of which was to show that the late Emperor of the French died from poisoning with chloral. The communication is interesting, especially the following statement: "The action of the chloral upon Napoleon was to produce great depression, followed by a profound euthanasia that ended in an eternal sleep—the sleep of death."

ITEMS, ETC.

The Death of Dr. Samuel H. Olmstead, of Brooklyn, took place on Friday, the 22d inst., from cerebral hemorrhage. He was born in New Haven about sixty years ago, and was educated at Yale College, both in arts and in medicine. He took his medical degree in 1861. He served as a medical officer of the army during the greater part of the War of the Rebellion, and reached the rank of brigade surgeon. He then established himself in practice in the southern district of Brooklyn, and early gathered to himself a select and appreciative clientele. He was for a time a member of the surgical staff of the Long Island College Hospital.

The Death of Dr. S. Guttman, of Berlin, is announced by cable as having occurred on December 22d from influenza. He had been the editor of the *Deutsche medicinische Wochenschrift* since 1885, and held the rank of privy councillor.

The Brooklyn Board of Health.—The mayor elect of Brooklyn has announced, among other proposed appointments, that Dr. Z. Taylor Emery has been selected to be the head of the department of health, to succeed Dr. J. Griffin, who has been in office since 1888. Dr. Emery is an ex-president of the Medical Society of the County of Kings.

The Clinical Society of the Elizabeth, N. J., General Hospital.—At the last meeting, on Tuesday evening, the 12th inst., Dr. T. N. McLean read a paper on the *Ætiology and Treatment of Pulmonary Tuberculosis*.

The Shooting of M. Gilles de la Tourette, concerning which some of the French newspapers seem to have built numerous fanciful theories as to the assailant's motive, appears to have been simply the act of a lunatic, according to our Parisian medical contemporaries. We are glad to learn that the ball, having struck the occipital bone obliquely, became lodged outside the bone and was readily removed.

Change of Address.—Dr. J. N. Bartholomew, from Trenton, Ohio, to 52 Lincoln Avenue, Chicago.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 17 to December 23, 1893:*

KULE, JOHN S., Lieutenant and Assistant Surgeon, is relieved from further duty at Jackson Park, Chicago, Ill., from December 23, 1893.

CALDWELL, DANIEL G., Major and Surgeon, is hereby granted leave of absence for one month, to commence about December 22, 1893.

BANISTER, W. B., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect about the 20th inst.

Society Meetings for the Coming Week:

MONDAY, January 1st: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; Chicago Medical Society; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society.

TUESDAY, January 2d: New York Neurological Society; New York Obstetrical Society (private); Medical Societies of the Counties of Broome (quarterly) and Niagara (semi-annual—Lockport), N. Y.; Buffalo Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Hudson (Jersey City), and Union, N. J., County Medical Societies (quarterly); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore); Androscoggin, Me., County Medical Association (Lewiston); Chittenden, Vt., County Medical Society.

WEDNESDAY, January 3d: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Bridgeport, Conn., Medical Association; Penobscot, Me., County Medical Society (Bangor).

THURSDAY, January 4th: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Obstetrical Society of Philadelphia; Boston Medico-psychological Association; United States Naval Medical Society (Washington); Washington, Vt., County Medical Society (annual—Montpelier).

FRIDAY, January 5th: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, January 6th: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

ence is so direct that the physicians who received the calendar can not but know to whom you referred.

It has been our custom for several years to send to the medical profession throughout the United States portraits of eminent physicians and surgeons, and, inasmuch as their distribution has been scrupulously confined to medical men of good repute, no objection has been offered by those gentlemen whose likenesses we reproduced. Not a copy of this calendar, nor of any of our other numerous publications, has ever been sent to the laity.

Maltine is distinctly not a "patent medicine," nor has it ever been advertised to the public, and therefore we have considered it within our province to distribute portraits just as we have promulgated testimonials from the most eminent physicians and chemists in this country and Europe.

We have statistics to prove that ninety per cent. of the physicians of the United States prescribe maltine. This fact, in addition to the fact that we reach the patient *only through the physician*, would seem to amply vindicate our use of the likeness of a physician whose pictures are on public sale and have continually appeared in the public press, and who is well known as a public man.

The portraits referred to were not used to push the sale of our preparations, as was the portrait of Dr. D. Hayes Agnew, recently published by us. It will be remembered that we printed under Dr. Agnew's portrait a facsimile of his indorsement of maltine. Our only reason for publishing the portrait of Dr. — was because we thought it would interest his medical brethren, who have shown so high an appreciation of the series of likenesses we have already published.

We should like further to say that as soon as objection was made by him we suspended the distribution of the calendars, as we would not knowingly offend even one of the honorable profession to whom we are so greatly indebted.

THE MALTINE MANUFACTURING COMPANY.

Reports on the Progress of Medicine.

ORTHOPÆDIC SURGERY.

By HENRY LING TAYLOR, M. D.

Scoliosis.—A good deal of attention, especially in Germany, has lately been paid to improved methods for the forcible correction of resistant lateral curvatures, and the subject is practically treated of by Dr. Bradford and Dr. Brackett in a recent paper (*Boston Medical and Surgical Journal*, May 11, 1893). The authors use a modified Hoffa's standing frame for applying pressure to the two prominent parts of the thorax, and put on a fixed plaster jacket while the patient is in the frame. When the limit of improvement by these means is reached, a laced paper jacket, according to the method of Dr. Weigel, of Rochester, is employed, and the use of the correcting frame is continued as an exercise.

The authors also describe a correcting frame for use in the recumbent posture. They state that "by no means of forcible correction can vertebrae already altered in shape be restored to shape or entirely corrected," but they report favorable results, especially where faulty attitudes constitute the danger of an increase of the curvature.

Scoliosis and Flat-foot.—In an investigation of 1,000 hospital patients, Dr. L. Heusser found (v. *Langenbeck's Archiv*, vol. xiv, No. 4) that, of 663 men, 188 had scoliosis, making twenty-eight per cent., while there were 147 cases among 337

Letters to the Editor.

THE PUBLICATION OF PHYSICIANS' PORTRAITS.

NEW YORK, December 26, 1893.

To the Editor of the *New York Medical Journal*:

SIR: Your reference to our calendar for 1894 demands our attention. While you did not mention us by name, the refer-

women, making forty-three per cent. There were also 283 cases of flat-foot, equally divided between the sexes. Of these, 283 flat-footed individuals (fifty-nine per cent.) had scoliosis, while of the 717 not flat-footed, only twenty per cent. had scoliosis. Half of the scoliotic patients had flat-foot also.

For comparison, 250 children from the asylums were examined, of whom 64 had scoliosis and 65 flat-foot. Of the boys, eighteen per cent. had scoliosis, and of the girls, twenty-six per cent.

Of the 185 who did not have flat-foot, 40, or one fifth, had scoliosis, while, of the 65 who were flat-footed, 24, or more than one third, had scoliosis. Bowlegs or knock-knees were found in five per cent. of the children who had the spinal or foot deformity, but only in one per cent. of those who had neither scoliosis nor flat-foot.

The author notes that scoliosis is found in robust and muscular individuals as well as in the delicate and anæmic, but he believes that the cause is to be found in rachitis. He recommends the use of a couch combining head and shoulder extension with a system of padded bands for lateral correction. The direction and amount of force applied by the bands is determined by appropriate weights and pulleys. Children can bear this kind of correction for one to two hours daily.

Scoliosis with Sciatica.—The relation between sciatica and scoliosis is discussed (*Lyon médical*, Feb. 5, 12, 19, 26, and March 12, 1893) in an interesting paper by Dr. A. Françon, who relates six cases of "crossed" scoliosis due to sciatica, cured by the thermal treatment of Aix-les-Bains.

The author refers to sixty-seven cases of scoliosis due to sciatica, reported in medical literature, nearly all in Germany, France, and Austria, and occurring since 1888. Of these, fifty were of the "crossed" type, the convexity of the scoliosis being on the side opposite to the sciatica, while in fifteen patients the scoliosis was on the same side. In two of the patients the scoliosis was sometimes on the right side and sometimes on the left, and in one of these it could be shifted from one side to the other at will.

In the first class of cases—"crossed type"—a patient who has left sciatica, for example, perceives at the beginning of the affection, or after a longer or shorter time, that the upper part of the trunk is inclined to the right, and the weight of the body rests upon the right leg. There is sometimes a certain degree of kyphosis at the same time. The shoulders may be inclined from or toward the affected side. There is a difference of opinion as to the ætiology of this affection. The author believes that the attitude is instinctively assumed to ease the pain, and because of a paretic condition of the lumbar and gluteal muscles of the affected side. The deformity is proportionate to the intensity of the pain, and usually disappears on its subsidence. Exceptionally it may persist as the result of permanent shortening of the affected muscles. One case is reported where the deformity remained after fourteen years, and another after eighteen. In one patient there was right scoliosis with left sciatica at the age of thirty-five years and left scoliosis with right sciatica twenty years later.

Scoliosis of the same side is variously explained as being due to reflex spasm of the muscles supplied by the lumbar plexus of the same side, to the extension of inflammation to the meninges of the spinal cord, and to a position of greatest ease.

The treatment consisted of steaming, followed by the hot douche and massage. After a few days a douche of lower temperature was used. The author found a rheumatic history in most cases, and remarks that the same treatment is not always applicable.

Dr. F. Peterson gives the following résumé (*Am. Medico-Surgical Bulletin*, November, 1893) of the conclusions of Dr.

L. Mann (*Deutsch. Arch. f. klin. Med.*, July, 1893) from a study of forty-seven cases of sciatica of the ordinary form and six cases with scoliosis:

1. That sciatica is frequently accompanied by paresis, not only of the muscles supplied by the great sciatic nerve, but also of those innervated by other branches of the lumbo-sacral plexus.

2. The paretic muscles, as a rule, are only slightly atrophied, and exhibit little or no morbid change when stimulated by electricity.

3. Should the paresis reach the erector spinæ muscle, typical scoliosis, with the convexity pointing toward the affected side, ensues.

4. In sciatica the pain may be only one-sided, and yet a bilateral motor paresis may exist. In such a case, should the erector spinæ of the non-neuralgic side be involved, it is possible for a homologous scoliosis to occur—i. e., a scoliosis with the convexity directed toward the non-neuralgic side.

5. If the sciatica is accompanied by a bilateral paresis of the abdominal muscles, as sometimes occurs, lordosis may follow—a condition which may be called *ischias lordotica*.

Pott's Disease.—Dr. A. B. Judson points out (*Jour. of Surg., Gyn., and Obst.*, September, 1893), as has previously been done by Whitman and others, that the middle and upper dorsal regions of the spine are peculiarly exposed to mechanical strains, and that disease in those regions is more tedious and severe than in cervical and lumbar caries. The author sees in this circumstance "a striking illustration of the fact that recovery from articular osteitis is postponed by unfavorable mechanical environment," and an indication for the thorough employment of mechanical means to relieve the diseased bone of weight-bearing and of motion so far as may be. While not condemning the use of jackets of the materials in ordinary use, when more perfect apparatus is not available, the author prefers an antero-posterior leverage support constructed of mild steel, so that the degree and direction of pressure may be accurately applied and modified by the surgeon to meet the changing shape and conditions of the spine.

Division of the Tendo Achillis.—Modifications in this operation are described by Dr. H. A. Wilson (*Internat. Med. Mag.*, August, 1893), as devised by Mr. William Anderson and Dr. Weir Mitchell. According to this method, first practiced in this country by Dr. W. W. Keen, the tendon is exposed by a free incision, split longitudinally for a sufficient distance, and each half cut through at opposite ends and sides of the long cut, so that the tendon can be lengthened by a definite amount and sutured in the position of choice. Dr. Wilson suggests that tendons may be shortened in a similar manner. Dr. Trnka reports another method of tendon suture in the *Centralblatt für Chirurgie*, March 25, 1893. It is probable that most of the drawbacks of the simple subcutaneous section of the tendo Achillis would disappear—sufficient attention were paid to the mechanical after-treatment of the foot.

Hammer-toe.—At a recent discussion at the Société de chirurgie de Paris (*résumé in Revue orthopédique*, July, 1893) on the treatment of hammer-toe, favorable results were reported in thirteen cases from the operation suggested by Dr. Terrier in 1888. This operation consists in exposing the deformed joint by a transverse dorsal incision, cutting the extensor tendon and the lateral ligaments, and then excising the joint. This was followed in every case by an ankylized joint and the cure of the deformity. Most of the speakers approved the procedure.

Voluntary Luxation of the Patella.—Dr. PROCAS reports (*Revue orthopédique*, September, 1893) such a case in a boy of fourteen, who had had rickets and genu valgum, which per-

sisted to a slight degree at the time of the examination. The patient walked without limping, and only when the left knee was flexed to at least a hundred and forty-eight degrees, and the biceps was suddenly contracted by the patient, was the outward luxation effected. This was painless and complete, so that the patella lay on the external surface of the external condyle, its inner border pointing forward. By a voluntary muscular effort the luxation was easily replaced. The author believes that a rachitic deformity of the femoral condyles and genu valgum furnished the conditions which made the displacement possible.

Congenital Malformation of the Scapula.—One of the causes of high shoulder is believed by Dr. Kirmesson (*Revue d'orthopédie*, September, 1893) to be congenital malformation of the scapula. He reports two cases, one in a girl of eleven, the other in a girl of four; both had slight non-progressive sigmoid lateral curvature, one to the right and the other to the left. In both, the right scapula was considerably elevated and rotated so that the inferior angle was displaced outward. The author does not connect the displacement of the scapula with the lateral curvature, nor with muscular anomalies, but believes that a congenital deformity of the scapula is the primary cause. As the power of elevating the arm was interfered with in both cases, was the possibility of a birth palsy or infantile cerebral palsy sufficiently considered?

Oblique Osteotomy.—Professor Broca maintains that there are advantages (*Revue orthopédique*, July, 1893) in an oblique osteotomy in certain cases of ankylosis at the hip, and of genu valgum.

Traction in Hip Disease.—An interesting experimental study of the question, "Does traction distract?" has recently been contributed (*American Medico-surgical Bulletin*, November, 1893) by Dr. E. H. Bradford. He remarks that "slight motion, if all intra-articular pressure were removed, would not be as injurious as the exaggerated constant articular pressure without motion. An articular bone surface freed from pressure heals, as is seen in cases of amputation at the hip, when a carious acetabulum will be seen to cicatrize entirely."

Repeated careful experiments on the cadaver showed that, "when a force is applied sufficient to overcome the muscular resistance, distraction takes place, except when checked by the ilio-femoral ligament. When this is relaxed by putting the limb in a proper position, marked distraction can readily be made." He concludes, from the experiments on diseased hip joints in the living subject, "that traction in hip disease, if properly applied, distracts, and that distraction can be made by a traction force feasible in practice; that no distraction takes place under a traction force of a few pounds."

The examination of pathological specimens shows that the head of the femur in hip disease is pressed against the acetabulum in a direction upward and backward, and traction should be applied in the opposite direction.

"As pathological evidence is conclusive that distraction, if possible, would be advantageous in treatment, it is impossible to avoid the inference that, in the treatment of hip disease in the active stage, distraction should be employed."

A pathological specimen is described, "which would appear to demonstrate that hip disease of a severe type, attended by supuration, can, if carefully treated by traction for years, be cured without subluxation, distortion, or enlargement of the acetabulum—a result not found in cases not treated, or treated without thorough traction."

The author found that traction at the knee was checked by the ligaments when the knee was fully extended; but he says: "If the knee is slightly flexed, so as to relax the strong fibers of these ligaments, traction makes a noticeable distraction."

Congenital Luxation of the Hip.—In order to study the pathogeny of this affection, Dr. R. Sainton reports (*Revue orthopédique*, July and September, 1893) the results of anatomical investigations into the structure of the hip joint in infancy. He finds that in infancy the neck of the femur is very short, and its diameter, as well as that of the head, relatively greater than in the adult, while the acetabulum is relatively shallower; the head is principally held in position by the posterior wall of that cavity. These characteristics are such that the head of the femur would be more easily luxated than in an adult; a comparatively slight malformation would suffice for the production of this result.

An arrest of the development of the borders of the acetabulum is probably the primary cause of so-called congenital luxations of the hip. This displacement does not always exist at birth, but is imminent if the above-mentioned condition is present. The cause of this arrest of the development of the cotyloid margin is obscure, but does not seem to exist in the premature ossification of the Y-cartilage, as has been claimed.

Congenital Hip Dislocation.—The treatment of congenital hip luxation, heretofore in the main unsatisfactory, seems to have made real progress, judging from the recent studies of several observers, notably Hoffa and Paci. The latter has given a full explanation (*Gaz. méd. de Paris*, March 25, April 1, 22, 29, 1893) of his method, which has been successfully practiced by others. The method consists in manual replacement under anæsthesia, and in holding the replaced bone in position by a fixation apparatus "until the opposing surfaces are reciprocally modeled" and form a more or less functionally perfect joint.

The replacement consists of four steps. The first is flexion of the leg on the thigh and of the thigh on the pelvis, in order to relax the muscles opposing reduction, and to bring the femoral head into the vicinity of the acetabulum. After flexion is complete the descent of the femoral head is assisted by pressure downward applied over the knee. The second step consists in a slow movement of abduction from the knee in its flexed position. This movement should bring the knee about six inches from the lateral plane of the body, and carry the femoral head forward near the space normally occupied by the acetabulum. In the third step, starting from the position last acquired, the leg is held flexed at a right angle and the thigh is slowly everted, with increased abduction, until the axis of the leg held at a right angle is perpendicular to the axis of the body. Having thrown the femoral head forward and inward into the cotyloid space by this manœuvre, the fourth step consists in a gradual extension of the thigh by the pressure of the hand upon the knee, while the other hand holds the foot, the flexed leg, and the whole limb in external rotation. With the head of the femur in the cotyloid space as a fulcrum, the anterior muscles are put on the stretch by this movement of extension, and their resistance must be gradually overcome; they will finally yield, and the leg will come down parallel with its mate, but eversion and a certain amount of traction must be maintained.

All the movements, and especially the last, must be executed with great care and deliberation. In some cases the correction appears to be complete, but a shortening of from three eighths to three fourths of an inch usually remains, owing to the incomplete development of the acetabulum, which also permits a recurrence of the displacement if the thigh is flexed or everted. The after-treatment consists in applying a plaster-of-Paris splint to the limb and pelvis, to maintain the corrected position. This is done while the patient is still anæsthetized, and the limb is pulled down and strongly everted; sometimes the limb is also abducted. A weight of from eight to twenty pounds is also applied to the leg. This apparatus remains on for a month, and

the extension with the weight is continued for three months longer. After this the limb is bandaged and the patient walks on crutches for four months, but extension is continued at night. After walking another four months with a cane, the patient is allowed to walk without support, other than a body brace.

The author reports ten patients, between the ages of eight and sixteen, treated by his method between 1886 and 1891, in all of whom there was a marked gain in the position and function of the limb.

Miscellany.

Scientific Teaching in Medicine was the title of an introductory address delivered at the opening of the session of 1893-'94 of the Medical School of the Catholic University, Dublin, by Dr. C. J. Nixon, professor of medicine, and published in the *Dublin Journal of Medical Science* for December. After some introductory remarks, the author proceeded as follows:

"*A School of Medicine an Object of Public Interest.*—I would first of all point out that it is quite an error to suppose that the progress of a school of medicine is a matter which concerns only those who are responsible for its organization. Its progress much more closely concerns the public at large. It is here that young men are taught that which is the aim and business of their lives. They come to us young and inexperienced, impressionable for good or evil, and upon the lessons which they learn, and the habits of thought they acquire, depends the course of their future, whether that be one of usefulness to their fellow-man and honor to themselves, or one of failure and disappointment. Apart, too, from its teaching purpose, a medical school fulfills another function. It is a center in which is collected a number of earnest and thoughtful men, each one interested in the progress of his own special department, adding to the storehouse of facts, and aiding by investigation and research the aim of medicine in relation to disease and its prevention. It is scarcely possible that the work of such men can be without influence upon their fellows, or that the community at large will not be the gainers by their labors. A school of medicine, like the university of which it forms a part, may be regarded as a fair index of the intellectual life of the nation, and no small degree of material prosperity or the reverse may be traced to its success or failure. The nature of the work done in it may, too, be regarded as a measure of what is taking place in the world at large from the fact that medicine is probably more sensitive to changes outside itself than any other branch of human knowledge. It deals not alone with physical but with psychological phenomena—with the social influences of wealth and poverty; peace and war; birth, development, and decay. Everything that affects the environment of the individual must influence the conditions of his mental and physical state, and so lead the physician into trains of inquiry, into the varying phenomena of existence, and the diseases that follow in their wake. For these reasons it is a matter of general interest to show how this school stands as a center of medical teaching, to analyze the work it has done, estimate our gains, note our defects, and formulate, if possible, schemes for their redress.

"In endeavoring to point out the present position of medicine, considered only in its scientific aspect, I need hardly say that the description attempted of the successive stages of development of each branch must be sketchy in character, and that only those developments which mark eras in progress can be noticed.

"*The Scientific Position of Medicine.*—It will be conceded by all that the present position of medicine as a science depends upon the progress which has been made, especially during the latter half of the present century, in those subjects upon which it rests, as on a tripod—viz., anatomy, physiology, and pathology.

"*Anatomy.*—Of anatomy, I need say but little. It holds, and always will hold, in medicine the position of being the keystone of the arch, the basis upon which are built all other branches of medical knowledge. Without an accurate idea of the conformation of the body, and of its integral parts, it is obvious no insight could be acquired into the functions of the various organs and tissues, and the mode of their development. From structure to function is a natural transition, hence the anatomists may claim that by their earnest, patient, and continuous efforts, they have laid the foundation for physiological research. Early in the present century the microscope was introduced as an instrument of investigation, and by its means, chiefly owing to the labors of Bowman, the study of minute anatomy or histology, especially in reference to embryology or development, gave so great an impetus to the entire subject that it may be said to have placed it almost on a level with the exact sciences. By the aid of the microscope, Schleiden discovered the cellular structure of vegetable tissues, while a little later on Schwann demonstrated the fact that all living structures are made up of minute particles of living tissue called cells, which, subsequently, the physiologist determined to be the seat and source of all forms of vital activity. It was about the same time that Mohl gave the name of 'protoplasm' to the hyaline material which forms the lining of cells in plants, a term subsequently given to the essential constituent of all living structures.

"It is scarcely necessary to dwell further on the light which was shed upon the various structures of the body by the study of histology. No branch of human knowledge represents more thorough and painstaking investigation than does this one—there is none that testifies more to the wondrous power of man in unlocking the mysteries of Nature. Whether we are to regard anatomy in the light which it throws upon the processes of development, or in that which it sheds upon the structure of such intricate organs as the eye, the central nervous system, the various glands, etc., it is impossible not to recognize its study as the foundation upon which the superstructure of medicine is built; and it is because the foundation has been well and carefully laid that the edifice raised upon it has such strong and goodly proportions.

"*Physiology.*—Turning now our attention to physiology, we find that, unlike the progress which has been made in anatomy—a progress which has been steady, and, except at the time of the introduction of the microscope into use, free from those convulsions of thought which constitute epochs or eras in the history of a science—physiology has developed not by stages, but by bounds, each period of change revolutionizing that which was learned or taught beforehand. In 1628 Harvey discovered the circulation of the blood, an event which led at the time to a scientific *renaissance*. Before this the crudest notions prevailed with regard to the processes of life. The idea of the circulation was that the blood swayed backward and forward in the veins 'like the tide of Euripus between Attica and Euboea.' At this time anatomy was but in its infancy, chemistry and pathology were almost unknown, and the knowledge of zoology and botany might be said to be confined to that obtained by studying the natural history of drugs employed in the treatment of disease. Some degree of order in thought resulted from Harvey's discovery; it gave a special stimulus to the study of anatomy, and awakened an interest in the study of

physiology which, under the deductive method of inquiry, led to considerable speculation regarding the origin of life and the vital functions generally. The progress made was, however, slow and unequal. Theorizing took the place of observation. It was considered an evidence of high intellectualism to philosophize; to observe or experiment was regarded as fitted only for those of inferior mental mold.

"The Relation of Physics and Chemistry to Physiology."—When, however, physiology by a gradual process of transition became a science of induction, when observation and experiment were made preliminaries to induction, Helmholtz mentions some curious instances which may be cited as showing the position physiology then held, and the prejudices which it had to overcome. He, himself, was strongly urged by a colleague in the university, who interested himself in the reorganization of the medical school, to divide the subject of physiology so as to be left free to devote himself exclusively to the intellectual part of it, while the experimental part could be undertaken by a colleague of inferior mental caliber, but quite good enough for that purpose. Not long before it was thought that to examine with the stethoscope was a crude method of investigation, that it lowered and debased the patient, who was after all a human being, and that a physician with a clear mental vision did not need such aid. In reference to the use of the ophthalmoscope, a celebrated surgeon gave it as his opinion that it was dangerous to allow crude light into the eye; while another said that it might be useful for physicians with bad eyes—his, however, were good, and he did not need to use it. These are instances which show how much the tendency of opinion at the time was against the use of experiment as a means of investigation of phenomena. Authority and prescription dominated procedure both in practice and in teaching. But an unseen force was steadily leading up to an inevitable change in the methods of inquiry. The study of natural philosophy had attracted the attention of the keenest intellects; the laws which had been discovered in mechanics, hydrostatics, optics, acoustics, electricity, and magnetism, began to be applied in the explanation of the processes of life, and the experimental methods employed in the physical laboratory were borrowed by the physiologists to determine the mechanics of the circulation, the laws relating to muscular and nervous responses to stimulation, the processes of absorption, and the phenomena affecting the special senses. About the same time chemistry had been making rapid strides, and great attention had been given to the study of organic bodies with the result that many which had been regarded as the product of vital processes were made in the laboratory. It soon came to be recognized that, for the most part, conditions which were supposed to be the result solely of vital energies, were capable of being split up into processes identical with those met with in the non-living world, so that, with some notable exceptions—especially those relating to absorption and certain nervous phenomena, and with the full admission that physiology can never become more than a mere branch of physics and chemistry—we have come to recognize that the true method of studying a vital phenomenon is to analyze it into its *measurable* physical and chemical constituents.

"It is not difficult to realize the effect of the application of these sciences to the methods of physiological inquiry, and the origin and scope of modern physiology dates from their use. It dates from the time of Joannes Müller, of Berlin, followed by those whose names are household words to us all—Brücke, Du Bois-Reymond, Ludwig, and Claude Bernard. It is important to note that nearly all these great men were physicists as much as physiologists, and that most of the methods of investigation employed by them have been designed and in most in-

stances made by themselves. With these notable exceptions, it may be said that to these men alone is due the scientific position held by physiology at the present day, though England can claim, through three of her sons, that she, too, has made three landmarks in its history—the circulation of the blood discovered by Harvey, the functions of the anterior and posterior roots of the spinal nerves by Sir Charles Bell, and the reflex function of the nervous system by Marshall Hall.

"What Medicine owes to Experimental Physiology."—In the routine practice of medicine and surgery we are apt, perhaps, to lose sight of what we owe to physiology, especially to experimental physiology. From experiments upon animals we have learned the mechanism of the sounds of the heart, the position of each sound in the cardiac cycle, and the conditions of the cardiac muscle. To these experiments we can trace most of what is known regarding the pulse; the conditions which affect its rate and tension. So, too, with the phenomena of respiration and the causation of cough. In studying the different forms of paralysis of the cranial nerves, we are utilizing the researches of Reid; in observing lesions of the vaso-motor system, we are dealing with phenomena which attracted the energies of men like Pourfour du Petit, Schiff, Goltz, and Gaskell; in noting disturbances affecting the brain and spinal cord, we are drawing from the information supplied to us by the experimental observations of Hitzig, Fritsch, Ferrier, Brown-Séquard, Marshall Hall, and Charles Bell. I do not in any way exaggerate when I affirm that all that is exact in medicine which refers to organic function is based upon the results obtained by painstaking and laborious experimentation. So great has been the progress made, so difficult is it to master all the facts that have been ascertained before any further development can be made, or fresh fruit garnered by those who represent continuity of work in this branch of medicine, that physiology has necessarily become specialized as a subject of teaching, and no modern school can afford to permit any teacher to deal with it without requiring that he should give to it his undivided attention.

"The Influence of Physiology on Pathology."—The influence which the study of physiology has exercised upon its twin sister, pathology, is easily understood. As physiology is the science of normal function, so pathology represents to us the deviation from the standard, the points of departure from health, the causes which produce such aberrations of function, and their effects upon the organs and tissues of the body. A few words will suffice to deal with the progress made by pathology during the century. Like physiology it, too, has had its periods of revolution, one of which may be regarded as probably the most pregnant of potentiality in the history of medicine—viz., the study of those minute vegetable cells known as bacteria, and their effects when grafted on the human organism.

"In 1760 Morgagni published his celebrated treatise, in which, for the first time, the attempt was made to localize disease to *particular* organs of the body, while a most accurate account was given of the anatomical changes produced as a result of the morbid action. There was, however, no attempt made by Morgagni to indicate with any degree of precision the ætiological factors in the production of disease. In the first decade of this century Bichat went a step further, and localized pathological changes in certain tissues of the organs of the body. Then came, late in the 'fifties, the epoch-making discovery of Virchow, who published his work on cellular pathology, a work which raised pathology from being, as it then was, a repository of dry, disjointed facts, disjointed in their relation to each other, to the rank of a science, a science based on etiology and constituting, in conjunction with therapeutics, the essential part of modern medicine. What a monument of work does not

Virchow's life represent? How keen and penetrating has been his vision, how cogent his reasoning! Starting with an investigation of all that had been done by his predecessors, whose researches and observations he verified for himself, he carefully extended the scope of their inquiries by physiological experiment and clinical observation until he obtained that result which now constitutes the cardinal element in the explanation of all diseased processes.

"Schwann and Goodsir had demonstrated the cell as the vital unit of all organized structures. Under normal physiological conditions these cells had to perform a definite function, retaining their original and characteristic forms so long as the function performed by them was normal. Virchow, by a careful study of the life-history of the cells, noted certain changes occurring in them, connected these changes with perversion of function, and, working still further backward, was led to study the altered condition of growth and environment that determined both alteration of function and of structure. He thus established such a correlation between normal and pathological biology, that in many cases it was almost impossible to determine where the one becomes merged into the other; and, furthermore, he showed that the marked changes observed in the altered cells, tissues, and organs of the body were shown to be as much the result of altered environment as the cause of perverted function. The effect of Virchow's teaching was far-reaching. When it was ascertained that the bodies of animals were composed of structures similar in many respects to the analogous parts met with in man, and that the cells composing these parts were also alike as regards their structure and function, comparative pathology became an object of close study and observation, culminating in those experimental researches which have influenced to so marked a degree our knowledge of disease and its treatment.

"*Bacteriology*—Meanwhile, as Virchow was pursuing his researches, a branch of biology, surpassing in the interest which surrounded it, was making steady progress—viz., bacteriology, adding another to the quota which all branches of human knowledge pay to medicine. We have the authority of Bacon that, even in his day, it, above all the other professions, could claim the palm for learning. How much more can this distinction be claimed for it to-day! When Latin served the purpose of welding all Western races together, it was the language of medical literature. Medicine alone, among the faculties of a university, has an unbroken tradition of over two thousand years from the Greek; it retains even still the relics transmitted to it by the physician of Cos. I have touched on the contributions which it has exacted from the natural and experimental sciences, while to pathological medicine in particular every branch of biology must bring a part of its treasures—anthropology, ethnology, and comparative anatomy. Thus we can see, as has been well said, at one end peoples, nations, and races; at the other a tiny speck of nucleated protoplasm, which not alone appears capable of supplementing our knowledge of the larger units which constitute the organs and issues of the body, but the study of which is probably destined, more than any force we know of in Nature, to influence the future of the human race." . . .

"*Pasteur's Researches*.—The history of bacteriology so far may be said to be written in the life and labors of Pasteur, supplemented by the records of what has been done by Lister, Chauveau, and Koch. There is no tale of Jules Verne which is more capable of exciting the imagination than the story of Pasteur's work. Having demonstrated the dependence of fermentation of different kinds upon different living organisms, which he classified into those that live in air and those to which air is fatal—aerobic and anaerobic organisms—he formulated

his method of dealing with diseases affecting vinegar and wines, and almost at a stroke abolished the maladies affecting both. He next directed his attention to the investigation of the diseases of the silkworm, at the time when the silk husbandry in France was in a state of ruin. Having discovered the minute organisms which caused the disease in the blood of the worm, he followed them through all the phases of the insect's life—through the egg, through the worm, through the chrysalis, through the moth. As by an enchanter's wand, at Pasteur's bidding, the disease was almost eradicated. Then came his *Studies on Beer*, and subsequently those observations and experiments upon the germ theory of disease which led him to adopt the principle of *virus attenuation* in the treatment of such diseases as fowl cholera, anthrax, quarter evil, and, finally, hydrophobia. Meanwhile, the clear mind of Lister was seizing upon the germ theory of fermentation and putrefaction. The organisms which produced both were in the atmosphere. If they came in contact with an open wound, pus formation was the result. A further fact was established by Lemaire in an adverse criticism of Pasteur's views—viz., that the presence of carbolic acid was inimical to the life of the higher animals and plants, and also to the lower organisms; the addition of a small quantity of carbolic acid to fluids in which fermentation and putrefaction ordinarily take place preventing the incidence of these processes. From these two data Lister built step by step the theory and practice of antiseptic surgery—a theory and practice which have saved thousands of lives and revolutionized the treatment of wounds and the routine of surgical practice." . . .

"*The Action of Bacteria in Disease*.—Before leaving the subject I may be permitted to mention an instance suggestive of the rôle played by bacteria in disease. We know that in the process of fermentation yeast grows and multiplies by extraordinary activity, splitting up the sugar into CO₂ and alcohol, till its further progress is arrested by the alcohol which is a product of its own activity. It is precisely similar with bacteria, when taken into the body as in any infectious fever. The organisms multiply at the expense of the fluids of the body, form ptomaines which, like the formation of alcohol in fermentation, bring the action of the microbes to an end. It is to the presence of these ptomaines in the blood that we may attribute the feverish disturbance that is set up—a disturbance unfortunately that is often fatal to the host as well as to the invader. An interesting experiment serves to show how the cells of the body resist the invasion of bacteria. A small quantity of a culture of known virulence was injected into a rabbit; a local inflammation followed, terminating in the formation of a small localized abscess, but no other bad effects followed. In another rabbit a similar injection was given, but, at the same time, a quantity of chloral was injected sufficient to paralyze the leucocytes; general infection rapidly followed, and the animal very soon died. In this instance it was found that the leucocytes examined on the warm stage showed no change of shape, and were perfectly sluggish in their movements. They took no notice of the bacteria when introduced into the subcutaneous tissues, and these then passing into the lymphatic spaces, ultimately reached the circulation, and so led to their wide-spread diffusion through the different organs with an attendant fatal result. This experiment may be taken as suggestive of the way in which the effects of alcohol taken to excess, or a poisonous influence of a like kind, may lead to an attack of fever, erysipelas, or some septic disease.

"*Bacteria in Relation to Animal Plagues*.—Two instances may be mentioned to show how the progress made by bacteriology has been utilized in the removal of animal plagues. Some eighteen months ago a plague of field mice in Thessaly and its

neighborhood had assumed such proportions that an entire field of corn was destroyed in a night. Loeffler, who has made such important researches in connection with the organisms of diphtheria, discovered a bacterium, the *Bacillus typhi murium*, which is pathogenic for mice of the species *Arvicola arvalis*; the field mice in Thessaly belonged to an allied species. Preliminary investigations showed that the bacillus was fatal to these also. A culture fluid was carefully prepared, and to this were added pure cultures of the bacillus. It was first shown that the bacillus was harmless to all domestic animals and to man. Peasants came from different districts, each bringing with him a basket of broken bread, which was steeped in the inoculated fluid, and the peasants were dismissed with instructions to put into each mouse-hole a portion of bread. The mice ate freely of the impregnated bread, with the result that, after some days, dead and dying mice were found scattered through the field. In less than four weeks the plague had disappeared, and the harvest was saved. Professor Bilgard, director of the research station in San Francisco, records a similar procedure, which rescued the country from a destructive 'field bug' of a species akin to the Colorado beetle.

"*The Future of Medicine Dependent on Pathology and Bacteriology*.—Of the field that is opened up in connection with preventive medicine, and in the treatment of such diseases as cholera, tuberculosis, tetanus, diphtheria, typhoid fever, and infectious diseases generally by the study of bacteriology, it would be at present rash to speak. Much has been done, great advances have been made, and great principles established. It may not be many decades distant when some startling results will be attained. To my mind, it is to bacteriology and pathology generally that we must look for the future of medicine. Fortunately, the methods of inquiry employed, those necessary for the progress, nay, for the existence of the human race, have stood well the strain fomented by misguided and ignorant faddists, but the issues at stake are too vital to be imperiled by what Sir William Gull described as the greatest cruelty in the whole world—the cruelty of ignorance. Experimental physiology and pathology have simply shared the fate which attended great discoveries in science, arts, and medicine. In the last we have had the spectacle of Vesalius, the great reformer of anatomy, being formally cited before the theological faculty of Salamanca, and Servetus being burned at Geneva with his book in which he described the circulation through the lungs. For a considerable time after the discovery of the circulation by Harvey, the treating of his doctrine was proscribed by the University of Paris, and to believe in it led to expulsion from the university and forfeiture of degree. Nor can it be said that the errors taught have been confined to the ignorant. Kant was so blinded by prejudice as to denounce vaccination as 'the inoculation of bestiality.' History is always repeating itself, and so the men of progress in medicine have had to take their share of contumely and bear more than their share of malice and misrepresentation from the anti-vivisectionists. They have stood their punishment, for the most part, with the stoicism of the ancient martyr. Yet the provocation to retaliate has been great. Scarcely any great advance in the doctrine of immunity has been made without the individual workers undertaking the risk of watching in their own persons the effects of inoculation of attenuations of the most deadly poisons.

"Quite recently Haffkine, in order to test the value of protective inoculation against cholera, inoculated himself with an attenuated virus of the disease. Very considerable constitutional disturbance, lasting for six days and attended with a rise of temperature, resulted. Hankin, and some eight others, also submitted themselves to the inoculation experiments, and with like results."

Medical Teaching in Various Countries.—At a meeting of the Suffolk, Mass., District Medical Society, held on October 28th, Dr. Charles F. Withington, instructor in clinical medicine in Harvard University, read a paper entitled *Medical Teaching in Germany*, which is published in the *Boston Medical and Surgical Journal* for December 14th. He remarked that Americans who were likely to consider the subject of medical study in Europe fell into three classes, and proceeded as follows: There were, first, "the small number of those who, either having received their general education abroad, or having been impressed with the excellence of European medical teaching, decide to take their entire course of medical study and their degree at some European university. I can not," he said, "but look upon this as an error for those who intend to practice in our country, for such men find themselves on entering upon their professional career at home at a disadvantage in the following ways: Their therapeutic armamentarium is rather different from that to which American patients are accustomed, and though they can, of course, readily enough learn the differences between the European and the United States pharmacopœias, yet they are likely to find that a good deal of the sort of medication which is swallowed with avidity or at least with resignation by the hospital patients of Berlin or Vienna, will meet with decided opposition from the self-respecting American stomach. Again, the man who has received his entire medical education abroad knows nothing of these professional traditions and usages to which patients here expect conformity, and which alone can make one's relations with his fellow-practitioners endurable. Finally, a lack of personal acquaintance with any of one's professional neighbors or with any of the older or more prominent physicians of the city or State where one is to settle, must be counted as a great disadvantage.

"The second and numerically the largest class of persons contemplating foreign medical study is composed of men who have taken their medical course and degree at home, but who wish further preparation for practice, and are considering whether they can best secure such practical experience as they desire at home or abroad. Yet it must be freely admitted that if these young men can afford but one year in addition to their required curriculum, a resident house-officership in a good general hospital offers advantages superior to any they can find under other circumstances in any country.

"Third, comes a class which I hope and believe is destined to become an increasing one—of men who, having already become established in practice, feel a need of temporarily interrupting their work by further study, with a view either to specialization, to consultation practice, or to such a picking up of lost threads, such a broadening of the professional horizon, as Harvard offers to her professors in the 'Sabbatic year,' but which we medical practitioners, while we need it quite as much as any other class of professional men, find it harder to get. If it is not possible to obtain it every seventh year, yet at a longer interval or for a shorter period, it is not, as I have reason to believe, impracticable. The practitioner who, with any of the motives I have just sketched, wishes to change temporarily his horizon, and to 'go to school' again, will generally, if possible, cross the water to get what he wants, despite the excellent polyclinic and post-graduate advantages that our large cities now offer. . . .

"Medical study in Germany differs from that in England and in our own country, in that it is always pursued at a university, where it shares in the broadening influence produced by the bringing together of various departments of learning about one common center. There are about twenty of these universities, the largest being those of Berlin and Munich. As the capital of the chief German state, Berlin stands easily the

intellectual center of Germany and probably of the world. Her university, though less than a century old, comprises nearly seven thousand persons and numbers among its professors some of the brightest lights in the firmament of science and letters.

"The German student of medicine passes to his professional studies either from the gymnasium, where he is supposed to have spent nine years in liberal studies, consisting chiefly of classics and mathematics; or he may come to medicine from the Real School, where modern languages and science replace the classical training of the gymnasia. The gymnasium, however, is held by the best medical men, and by the government also—if we may judge from the distribution of official patronage—as the only adequate preparation for professional study, the Real School being considered as an educational concession to the popular element. As the gymnasium takes boys at an average age of about nine, they are ready at eighteen or at nineteen (adding the year for compulsory military service) to begin their medical studies, unless they choose, as a few do, to take some semesters with the philosophical faculty of the university before passing on to the medical. Unless they do this, their basis of general culture is less than that of our best medical students, for the gymnasium can not be held as at all equal to our best American colleges. On the other hand, the Germans gain two or three years in time over our college and medical students.

"The required medical course occupies eight semesters (four years). At the end of the second year comes the first examination, the *tentamen physicum*, which covers chemistry, organic and inorganic, mineralogy, physics, botany, anatomy, physiology, zoology, embryology, and histology. Near the end of the course occurs the examination on the other usual subjects of medicine, for the doctorate, or medical degree, in case the student chooses to apply for it. But as it is in many cases held to be a useless luxury, being rather expensive and quite unnecessary for medical practice, the student often reserves his money and energy for the state examination, which is essential to engaging in medical practice, which is a severe examination, conducted by government officials, and which makes of every successful candidate in a certain sense an officer of the government and invests him with corresponding authority and responsibility.

"I do not believe that the average German medical student is as well equipped as the average graduate of our best schools, that is, those having a four years' course. For, in the first place, the time of actual study is not so long. The winter semester nominally lasts from October 15th to March 15th, and the summer semester from the middle of April till the middle of August. Here are apparently nine months of term time. But no pretense is made of beginning work before November 1st or of continuing it after March 1st. In fact, the 'vacation courses' begin March 1st, two weeks before the close of the regular term for which the students have paid. The same amputations are applied at both ends of the summer semester, and when to these lengthened vacations we come to add a two weeks' holiday at Christmas, and the first, second, and third days' celebration of the various religious and secular festivals, there is probably not left more than seven months net out of the twelve for work.

"Again, our academic 'hour' for teaching purposes is fifty five minutes. In Germany, the first fifteen minutes are always thrown off and the remaining forty-five minutes are, according to my observation, often considerably further reduced. So that the German lecture or clinic averages from twenty to twenty-five per cent. shorter than our own.

"As to the instruction, it is generally admirable. The ex-

amination is thorough, the diagnosis shrewd, the literature discussed voluminous, recent, and widely drawn. But despite, or perhaps because of, the excellence of the elucidation, the average student gets probably less advantage from it all than he would from trying to unravel a few obscure cases for himself. To be sure, he serves his time as *Praktikant*, when he makes more or less for a 'snap' diagnosis. But he rarely works up a case in careful detail. His point of view is not so much the bedside as the lecture benches, for, at least in Berlin, he rarely gets into the hospital wards. He does not read very much, and evidently sets great store for his examinations upon the careful pen-and-ink notes which he has kept of all the cases he has ever seen. In a word, he is made the subject of a constant intellectual *gavage*, in which, if you will allow the figure, the pabulum is of the best quality, and is fed to him with an unsparing hand; but it is so thoroughly predigested that very little work is left for his own intellectual powers to do, and they are likely to develop less activity than might otherwise be gained.

"Conditions like the foregoing, which are not specially favorable for the student who is learning to make diagnoses, are, on the other hand, of advantage to the practitioner. From the latter point of view, the abundance of clinical material is very useful. Not only is the material very great in every European city where a large portion of the population is so poor that it must receive medical aid in sickness, but it is exceedingly available. Patients are always willing to be shown, being generally treated with fair consideration, and even when the visitor notices something lacking in this regard, it must be confessed that the patients themselves do not generally appear to be aware of the omission. Post-mortem examinations are, of course, made in all fatal cases, and hence clinical study is never subjected, as must often happen in America, to the incompleteness due to lack of pathological evidence.

"The chief clinical teachers can, when they wish to illustrate any particular point, bring forward an immense amount of material. For instance, Mendel is said to have shown at one demonstration of epilepsy thirty-five patients in an hour. Certain of the medical *causes célèbres* make a living by going about from clinic to clinic, the fact that they are already under treatment with one clinical teacher making no difference in their acceptability to another. Special attractions are sometimes even sent for and fetched in a carriage like our coy voters on election day.

"To work up properly such immense amounts of material involves tireless industry, and perhaps this is the most striking characteristic of the great medical teachers of Germany. The *breadth* of knowledge of such a man as Senator is something almost incomprehensible. If it be true, as has been said, that Vienna stands for specialism in medical training, it is also true that Berlin stands for breadth of medical learning. Senator's work covers not only the usual field of clinical medicine, but nervous diseases equally well, while at his polyclinic one of his most popular exercises is in connection with the diseases of children. Of course, much of the work, bacteriological, microscopical, and clinical, is prepared by his assistants, but one feels that it is all done under his personal orders and supervision, while his incessant stream of publications indicates over what a long frontier of medical science he is pushing forward his explorations. . . .

"The subjects best taught in Berlin are probably internal medicine, which I have just referred to, nervous diseases, and bacteriology. . . .

"In the youngest of the medical sciences, bacteriology, Berlin occupies, as is well known, a leading position. To illustrate at once what is being done in this branch, and at the same

time to serve as an example of the thoroughness with which the Germans organize and carry on scientific investigation, let us briefly describe one of the newest medical institutions of Berlin, one so new that many of my hearers who are familiar with that city have never seen it. This is the Institution for Infectious Diseases, which may be regarded as the first fruits, and perhaps thus far the most useful outcome of Koch's tuberculin discovery. In the enthusiasm which followed the announcement of tuberculin, the government promptly voted the sum necessary to carry out the enterprise, and the institution was opened in August, 1891, with Koch as director, and a large staff of skilled assistants, among them Pfeiffer, Behring, and Brieger.

"The institution is situated just west of the Charité Hospital, and covers a tract of land about six hundred and fifty feet by two hundred feet in dimensions. It comprises seven wards or barracks of most approved hygienic construction, having all necessary kitchen and service rooms, baths, closets, etc., a general ward, isolating rooms, and a sun-room or sitting-room for patients who are able to be up. These provide for men, women, and children suffering not only from such contagious diseases as diphtheria, but from tuberculosis in all its forms, including joint affections and lupus. One building has even been utilized for variola, while others contain puerperal fever, and even influenza-pneumonia. Rather too heterogeneous a mixture of infections, we may say, for the good of the patients treated; but a tolerably good isolation is practiced, and the grouping of so many infections directly about the center of bacteriological research gives obvious advantages for study. In the administration building is a small amphitheatre for lectures, having, among other equipments, a stereopticon and white screen for the display of microphotographs.

"Behind this building stands another, which serves two important purposes: first, that of disinfection. The articles (clothing of patients and bedding from the wards) go through a regular order of rooms into and out of the steam disinfection apparatus, and the disinfector himself is subjected to a bath and change of clothes between the times he loads and unloads the apparatus. Under the same roof, but securely separated, is the autopsy room, where the director personally assigns to various members of his staff the work—bacteriological, chemical, and microscopical—which the case demands. . . .

"The educational value of this institution is, of course, greatest to the regular staff of workers, including those under physicians who are detailed to this duty from the Charité. But their work is, through publication, made the property of the scientific world, while men are always going out from it, as did the clever Japanese, Kitisato, to extend the work in other lands.

"For the average student who goes to Berlin to study bacteriology, the Hygienic Institute is a more available place for personal practice in bacteriological work. In this building is maintained the sanitary watch and ward over the city. Regularly every two weeks are brought hither specimens of drinking water from each of the eleven different stations which supply Berlin. These specimens are tested both chemically and bacteriologically, and if the filters (also devised in this institution) are found not to be doing their work, immediate attention is given to the matter. Here are good opportunities for practical study under the instruction of Rubner and Günther.

"Courses for beginners are organized several times in a year, each course occupying all the time—that is, eight hours daily, for a month. The work is so systematized that no time is wasted. Each man makes his nutrient media, plants and dilutes his cultures, stains and examines his growths, and in

general gets a *coup d'ail* at the subject, which, of course, is superficial, but which is of great service, at least in enabling one to judge of what the special workers in this department are doing. Other more advanced instruction, of course, is also given here.

"In closing, I have only a few practical suggestions to make to any contemplating medical study in Germany. In the smaller universities you will probably spend less money, learn more German, see fewer cases medically, and learn far less that is of interest non-medically.

"Having decided to study one or more semesters in Berlin, you can matriculate if you see fit, though it is not necessary. For this nothing is necessary but your passport as a citizen of the United States. Your medical diploma is not of the slightest use. Matriculation gives you a right to attend any 'public' courses, gives you some reduction of price at theatres and concerts, and confers a certain immunity against police arrest, which may be convenient if you are sportively inclined. Neither need you be deterred by age from matriculating, for you will find among your fellow-students white-haired men in the sixties. Matriculation costs about seven dollars in money and an hour or two in time. If a matriculant, you pay through the university *quaster*; if not, in person to the respective teachers for whatever courses you elect. The usual price for a private course occupying two hours a week throughout the term is five dollars, and for a more or less number of hours in the same proportion, so that fifty dollars for a term will pretty thoroughly fill one's time, twenty hours per week of private courses and as many public courses as one can get time for. There is also usually no objection to an occasional attendance at other clinics than those for which you are regularly enrolled."

The New York Society for the Relief of Widows and Orphans of Medical Men.—At a meeting of the board of managers held on December 20th, the president, Dr. Ellsworth Eliot, made the following remarks:

"Eleven widows and three children of deceased members relieved; \$6,610.30 added to the permanent fund, now amounting to \$189,157.06; the membership increased by thirteen, now numbering one hundred and forty-three; and all this at an expense of only \$180.30—such is the record of the last year, and it will compare favorably with that of any preceding one.

"In its foundation our society had for its model that of the same name in London, established in 1788, and such are our record and prospects that the mother need not feel ashamed of the daughter. Of course their capital—£88,057 10s. 6d. (about \$440,286)—greatly exceeds ours. They have had legacies from fifty-eight persons, three of £5,000 each (\$25,000), one of these, and the last of the three, being that of Sir Erasmus Wilson, the distinguished dermatologist, in 1887. Our benefactors number fifty-five, most of them having contributed \$150 each. The name in this list leading all the rest is that of Alonzo Clark, whose gift is estimated at \$20,000.

"According to the last publication of the London society, the allowance to a widow is £50 (\$250) and a Christmas present of £5 (\$25), making £75 (\$275) for the year. The largest allowance to their orphans is £12 (\$60) with a Christmas present of £2 (\$10), making the annual amount £14 (\$70). The provision in our by-laws for giving each child \$50 as an outfit at the time when the annuity ceases I do not find in their regulations.

"Their expenses last year exceeded \$1,200 (£247 3s. 10d.). Of this the secretary had \$630 (£126). The amount of our expenditure, as above mentioned, is \$180.30, our secretary being allowed an honorarium of \$50."

"Their 'grants and expenses' exceeded their 'total receipts

available for payments' by £73 6s. 4d. (\$366), this amount being their deficit. We added, as previously stated, \$6,610.30 to our permanent fund. Happily, our by-laws prohibit deficits. Their membership is three hundred and twelve—seven less than the previous year. The number of their widows receiving relief is fifty-eight, and the number of children twelve. The large number of the former is astonishing. Should our widows ever bear as large a proportion to our membership as is the case with the London society, we should be compelled to reduce the allowance, or gifts to our principal must be large and numerous.

"A great difficulty during the past year has been the safe investment of our funds at a fair rate of interest. We have had thousands of dollars for which we received but two per cent."

"The secretary of the London society informed me last summer that it required much effort to keep their numbers good and to make additions thereto. Such has been the experience of our society. For a number of years our members, according to the annual statements, were fewer and fewer. I believe that for several years not more than one or two persons have voluntarily sought membership. Those who have joined us have done so through personal solicitation. The energetic president of the New York Physicians' Mutual Aid Association, happily one of our board of managers, recently informed me that not more than six out of a hundred applied for membership in that society without personal urging. Printed documents and annual statements do not bring members. Physicians should make provision for themselves and any family they may leave. No one in our profession in our city need die in straitened circumstances. By the payment of from \$15 to \$20 in the Physicians' Mutual Aid Association, his representatives, in the event of his death, can immediately command \$1,000. After a suitable probation and not a large payment in our society he can provide generous relief for a widow and orphans, should they be in need of it. The medical profession in no city in the world, so far as I can learn, are as fortunate in this respect as the physicians in generous New York.

"Our board of managers is much the same as last year. Two faithful ones, Dr. Laurence Johnson and Dr. William T. White, whom death has removed, we shall greatly miss. Happy will it be for the society if their successors prove equally attentive to their duties."

The International Medical Congress.—Dr. A. Jacobi, chairman of the American National Committee of the Eleventh International Medical Congress, has received the following communications from the secretary general:

First. Papers to be read in any of the sections of the congress should be announced on or before January 31, 1894, to the secretary general, Professor E. Maragliano, Ospedale Pammatone, Genoa, Italy.

Second. The title of the paper ought to be accompanied with a brief abstract of its contents and conclusions.

Third. The programme to be distributed will contain the titles of all the papers announced before August 31, 1893, and since.

Fourth. The reductions granted by the railway companies months ago will be available from March 1 to April 30, 1894.

In the interest of such medical men as sail for Europe before official cards have been received from the general committee, Dr. Jacobi proposes to supply, in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. It is suggested, besides, that a passport may increase the traveler's facilities.

A letter of the secretary general's, dated November 29th, informs Dr. Jacobi that "traveling documents" will be sent to

the address of every subscriber on or before February 15, 1894; and after that date "congressists" will have to apply to Dr. Jacobi.

It also contains the following regulations of former circulars: Members' dues are five dollars (money order to Professor L. Pagliani, Rome); guests' (wives and adult relations'), two dollars; medical students', no fees. All are entitled to traveling documents. Reductions on the Italian railways are available from March 1st until April 30th.

The Therapeutic Uses of Exalgine.—In the *Lancet* for November 25th Dr. Thomas D. Savill gives details of a number of cases in which he used exalgine to relieve pain. The cases included rheumatic arthritis, cephalalgia, obscure abdominal pain, shooting pains in the head and neck in a woman suffering from cardiac valvular disease, gouty arthritis, traumatic epilepsy, etc. He says: "The drug can be readily administered in the form of a powder, especially put up in 'cachets,' or it may be dissolved in water to which a small proportion of spirit has been added, or even in pure water if this be used hot. In fact, the last-mentioned method of administration is, on the whole, the most convenient one, for if six fluidounces of boiling water are poured on to forty-eight grains of the crystals a clear solution containing eight grains to the fluidounce is formed, which does not precipitate in cooling; a teaspoonful of this solution thus represents one grain of the dry salt. This keeps well, is devoid of disagreeable smell or taste, and is in every way reliable. It will be seen that the diseases for which the patients were under treatment were various; and, speaking generally, it may be affirmed that in no instance did the drug give rise to any inconvenient or uncomfortable effects even in the presence of cardiac disease or phthisis, nor did it determine any symptom of intoxication. I think that, if care is taken not to administer the drug to patients with a febrile temperature or who are constipated, no ill effects are ever likely to be experienced. These are, at any rate, the conclusions which I have drawn from my experience."

Clinical Experience with Solutions of Pyrozone.—Dr. James E. Newcomb (*Jour. of the Amer. Med. Assoc.*, November 18th) gives his experience with pyrozone in both aqueous (three-per-cent.) and ethereal (five-per-cent. and twenty-five-per-cent.) solution. He says: "I have used the pyrozone three-per-cent. solution for cleansing the nose and nasopharynx whenever there have been crusts or inspissated secretions. The full strength has been employed anteriorly by a small pyrozone atomizer, and posteriorly with the ordinary hard-rubber syringe. It has not seemed necessary to dilute the solution. Care should be taken that it is slightly warm, as indeed should be all the cleansing agents supplied to these regions. On coming in contact with the tissues, it produces a momentary tingling which quickly subsides. In using this remedy, the impression has been forced upon me that we are not always as thorough in cleansing the nasal cavity as we suppose. Often I have used aqueous and oily sprays in the nostrils until they were apparently clean, but a succeeding syringeful of pyrozone, three-per-cent. solution, would start up little masses of white foam, showing that a little of the secretion was still hidden somewhere behind some projecting shelf in the nasal cavity. On enlarged glands at the base of the tongue, if isolated, the pyrozone, twenty-five-per-cent. solution, has given considerable relief to the symptoms incident to that condition. If the adenoid masses have been large and aggregated so as to form physically a true lingual tumor, the same objection has seemed to obtain as in the turbinated hypertrophies; but, after all, we have to remember that it is on dead matter, rather than on living tissue, that the remedy finds its own peculiar sphere of action."

THE New York Medical Journal.

A WEEKLY REVIEW OF MEDICINE.

EDITED BY

FRANK P. FOSTER, M.D.

THE PHYSICIAN who would keep abreast with the advances in medical science must read a *live* weekly medical journal, in which scientific facts are presented in a clear manner; one for which the articles are written by men of learning, and by those who are good and accurate observers; a journal that is stripped of every feature irrelevant to medical science, and gives evidence of being carefully and conscientiously edited; one that bears upon every page the stamp of desire to elevate the standard of the profession of medicine. Such a journal fulfills its mission—that of educator—to the highest degree, for not only does it inform its readers of all that is new in theory and practice, but, by means of its correct editing, instructs them in the very important yet much-neglected art of expressing their thoughts and ideas in a clear and correct manner. Too much stress can not be laid upon this feature, so utterly ignored by the “average” medical periodical.

Without making invidious comparisons, it can be truthfully stated that no medical journal in this country occupies the place, in these particulars, that is held by THE NEW YORK MEDICAL JOURNAL. No other journal is edited with the care that is bestowed on this; none contains articles of such high scientific value, coming as they do from the pens of the brightest and most learned medical men of America. A glance at the list of contributors to any volume, or an examination of any issue of the JOURNAL, will attest the truth of these statements. It is a journal for the masses of the profession, for the country as well as for the city practitioner; it covers the entire range of medicine and surgery. A very important feature of the JOURNAL is the number and character of its illustrations, which are unequaled by those of any other journal in the world. They appear in frequent issues, whenever called for by the article which they accompany, and no expense is spared to make them of superior excellence.

Subscription price, \$5.00 per annum. Volumes begin in January and July.
